15 **Abstract**

16 Understanding the morphodynamics of beach-dune systems requires knowledge of  
17 the spatio-temporal variability of the sediment transport system. It is common in  
18 aeolian studies to employ a single transect instrument set up, oriented parallel to the  
19 wind direction. This experimental design assumes that there is no significant  
20 variation in sediment transport lateral to this direction. A limited number of recent  
21 studies into this lateral (or spanwise) variability have revealed substantial differences  
22 in transport rates over very short spanwise distances (<4 m). Research investigating  
23 scales of 10 s of metres is even more limited. This paper examines alongshore  
24 variability of aeolian sediment transport at this scale. Data were collected over eight  
25 hours during an offshore wind event. Thirteen Jackson traps were deployed, co-

26 located with three-dimensional ultrasonic anemometers (UAs). The instruments were  
27 deployed in a grid covering an area of 55 m cross shore and 90 m alongshore. The  
28 data were analysed as 5 and 10 min totals, and were mapped for visual assessment  
29 of transport patterns. Alongshore variability was quantified using the coefficient of  
30 variation (CV). Results confirm identifiable spatio-temporal patterns in sediment  
31 transport. The CV results show alongshore variability ranging from 12% to 48%, with  
32 the lower beach traps showing much greater spatial variation. These values are  
33 comparable to earlier studies. The implications of recent research into secondary  
34 airflow patterns over dunes are discussed in light of the results presented.

35

### 36 ***Highlights***

- 37 - Addresses gap in field – data on alongshore variation in aeolian sediment  
38 transport.
- 39 - Data collected under offshore wind, adding to rare studies under these  
40 conditions.
- 41 - Results clearly identify cross- and alongshore spatio-temporal transport  
42 patterns.

46

### 47 **1. Introduction**

48 In beach-dune systems an understanding of the aeolian sediment transport system  
49 is critical to understanding the broader morphodynamic functioning of the system.

50 Numerous factors have been shown to affect rates of sediment transport (Sherman,

51 1995). These include fluid forcing variables, such as wind speed and direction  
52 (Arens, 1996, Jackson and McCloskey, 1997 and Leenders et al., 2005), and factors  
53 which control the erodibility of the surface (e.g., moisture content (van Dijk et al.,  
54 1996 and Wiggs et al., 2004) or grain characteristics (Arens et al., 2002 and Leys  
55 and McTainsh, 1996). Because all of these factors can vary over time and space it is  
56 to be expected that the resultant sediment transport will also exhibit spatio-temporal  
57 variability. Cross shore variability has been identified by many studies (e.g., Bauer et  
58 al., 1990), with zonation of the transport patterns apparent in some cases. Most  
59 studies, however, assume lateral variability – perpendicular to the airflow direction –  
60 in the fluid forcing (considered the primary controlling factor) is not significant enough  
61 to warrant designing experiments to assess this aspect. This has resulted in the use  
62 of single transect lines that are aligned parallel to the airflow direction  
63 (e.g., Davidson-Arnott et al., 2008, Hesp et al., 2005, Nordstrom et al.,  
64 1996 and Walker et al., 2006). This is also the case in many wind tunnel studies,  
65 where only one instrument line is common (e.g., Bauer et al., 2004, Butterfield,  
66 1999, Dong et al., 2004 and Rasmussen and Mikkelsen, 1998), in most desert  
67 studies (e.g., Baddock et al., 2011, Weaver and Wiggs, 2011 and Wiggs et al., 1996)  
68 and in the fluvial literature (Best, 2005). Another likely reason for the use of single  
69 transect lines is the common shortage of physical and human resources (Sherman,  
70 1995).

71 Where lateral variability has been assessed it has been found to fluctuate  
72 considerably. Gares et al. (1996) investigated alongshore trends in sediment  
73 transport during offshore wind events. Alongshore transport rates were assessed in  
74 comparison to spatial variations in a number of variables, including moisture,  
75 carbonate content, wind speed and sediment size. Wind gustiness (high variability in

76 speed and direction) and moisture appeared to contribute more to the variable  
77 transport rates than any of the other variables. Nordstrom et al., 2007 and Nordstrom  
78 et al., 2006 and Jackson et al. (2006) recorded high spatial variability in sediment  
79 transport over a 4 m distance for alongshore and offshore winds in a complex human  
80 altered beach-dune system. More recently Ellis et al. (2012) have reported  
81 substantial lateral variability in sediment transport rates at two separate field sites.  
82 Employing similar spatial (<4 m) and temporal (3–20 min) scales they demonstrated  
83 that lateral variability in sediment transport rates could lead to up to 100% disparity  
84 between predicted and observed transport rates if single point measurements are  
85 relied upon.

86 Recent research on secondary airflow dynamics and the role turbulent structures  
87 may play in grain entrainment have highlighted the complex nature of the forcing  
88 fluid flow itself. Topographic steering of alongshore winds towards the foredune  
89 (Walker et al., 2006), airflow stagnation followed by acceleration up the stoss slope  
90 and further steering or flow separation at the crest (Hesp et al., 2005), topographic  
91 steering or reversed flow on the lee side of dunes (Lynch et al., 2008, Lynch et al.,  
92 2009 and Lynch et al., 2010) have been recorded in coastal dune environments.

93 In theory, the spatio-temporal variations evident in airflow should be reflected in the  
94 sediment transport patterns. It is on this premise that Baas and Sherman  
95 (2006) investigated the lateral variability of sediment transport using statistical  
96 characterization analyses. Their field study found that variability increases with  
97 spatial scale, with impact sensors 4 m apart recording up to 266% differences in  
98 transport rates. These differences occurred under fairly constant wind conditions  
99 (within 15° of array normal).

100 While Baas and Sherman (2006) targeted an environment where a uniform boundary  
101 layer was expected, to date, no studies have been undertaken to incorporate recent  
102 advances in our understanding of secondary airflows in controlling lateral variability  
103 in sediment transport patterns.

104 The research reported here was designed to investigate if lee side secondary airflow  
105 structures that may occur during offshore winds result in alongshore variations in  
106 sediment transport on the beach. Delgado-Fernandez et al. (2011) quantified near  
107 surface airflow patterns under offshore conditions at the Magilligan Strand, Northern  
108 Ireland, using quadrant analysis to propose a quantitative model describing airflow  
109 reversal, transition and its re-attachment in the lee of a coastal dune. Findings from  
110 Delgado-Fernandez et al. (2011) were later used as a basis for Computational Fluid  
111 Dynamics (CFD) simulations, with results suggesting the nature of the airflow  
112 response in the lee of the dunes was not uniform alongshore (Jackson et al., 2011).  
113 In simulations, using a detailed digital elevation model of the site incorporating dune  
114 crest irregularities and dune lee side complex topography, heterogeneity within the  
115 secondary airflow patterns was evident. Zones of enhanced transport potential (i.e.,  
116 higher wind speeds close to the surface) were seen to alternate with zones of  
117 reduced potential, with spacing in the order of 10–50 m. While Jackson et al.  
118 (2011) presented wind simulations in three-dimensions their field airflow data was  
119 recorded along a single cross shore transect, making it insufficient for the purpose of  
120 investigating alongshore wind patterns in the field.

121 A field experiment was designed to assess spatio-temporal patterns of sediment  
122 transport and secondary airflow, under offshore winds. This paper reports on the  
123 variability of sediment transport on the beach [a companion paper reports the finding

124 regarding the airflow dynamics, with another companion paper reporting on the role  
125 turbulent airflow structures play in the initiation of sediment transport.

126

## 127 **2. Study site**

128 Magilligan Strand, Northern Ireland was used as a study site (Fig. 1). The beach is  
129 oriented along a north west – south east axis and is dominated by prevailing south  
130 westerly offshore winds. The foredunes are up to 12 m in height at the site and are  
131 backed by dune ridges of similar height. All ridges are densely vegetated  
132 by *Ammophila arenaria*. The slope of the foredune facing the beach (the lee side  
133 under off shore airflow) is abrupt and is thought to enhance airflow separation under  
134 certain conditions ( Beyers et al., 2010). The foredune toe section at the site had  
135 been accreting for a number of years at the time of the study, with embryo dunes up  
136 to 1 m height in place. The beach is generally planar, and up to ~100 m wide during  
137 spring low tides. Sediments consist predominantly of very well sorted, fine-grained  
138 quartz sand, with a mean grain size of 0.17 mm. The beach was relatively free of  
139 drift material and vegetation at the time of the experiment. The site was chosen  
140 based on previous observations of airflow separation and reversal during offshore  
141 winds. Recent research by Lynch et al. (2010) observed that different dune  
142 morphologies along Magilligan Strand interacted differently with the flow. Sharp-  
143 crested, high dune sections such as the one of the study site resulted in flow  
144 separation and reversal while more rounded, shorter dunes along the NW end of the  
145 spit resulted in deflection of attached airflows. Numerical simulations using CFD  
146 tools by Beyers et al. (2010) and Jackson et al. (2011), and field data presented  
147 by Delgado-Fernandez et al. (2011) confirmed the existence of clear patterns of  
148 airflow separation and reversal at this particular site.

149

### 150 **3. Methods**

#### 151 **3.1. Field measurements**

152 Data were collected over eight hours during an offshore wind event on 26 April 2010.

153 The surface was dry and relatively free of shell lag deposits, algae, and other debris

154 strongly affecting general transport dynamics. Micro topographical features such as

155 ripples developed before and during the experiment (Fig. 2). Thirteen continuously

156 weighing horizontal sediment traps were deployed. The traps are a modified form of

157 the Jackson trap (Jackson, 1996) where the tipping bucket mechanism was removed

158 and the load cell upgraded to hold approximately 3.5 kg of sand before it required

159 emptying. This greatly reduced data post processing time. The traps were co-located

160 with three-dimensional ultrasonic anemometers (UAs), each placed at a height of

161 0.5 m. (Fig. 2). The instruments were deployed in a grid covering an area of 55 m

162 cross shore and 90 m alongshore. Cross shore spacing between each pair of

163 instruments was 10 m. Additional traps were deployed along Transect B to give a

164 5 m spacing for this line of instruments. Alongshore spacing of the transects was

165 30 m, intended to sample zones of enhanced and reduced potential transport

166 suggested by Jackson et al. (2011). An anemometer (Gill HS-50 model) was also

167 positioned at the foredune crest at a height of 6 m (18 m above the beach surface).

168 All instruments were connected to an on-site personal computer and logged

169 simultaneously at 25 Hz. A total of 14 traps were deployed during this run, however,

170 instruments located in position D1 did not perform correctly and hence have been

171 excluded from the analysis. Instrument positions and survey data were gathered with

172 a Trimble 4800 Differential Global Positioning System (DGPS). Topographic

173 information of the beach surface as used to create a detailed digital elevation model  
174 of the study site (Fig. 3).

### 175 **3.2. Analysis methods**

176 The trap data were analysed as 5 and 10 min totals, and were mapped for visual  
177 assessment of transport patterns. The co-located anemometer data were used to  
178 infer transport direction. Anemometers were oriented in the field in similar directions  
179 with respect to North and levelled with respect to the horizontal gravity plane. Each  
180 anemometer was sampled at 25 Hz and provided time series of three components of  
181 the wind vector,  $u$  (streamwise),  $v$  (spanwise), and  $w$  (vertical). These were first  
182 averaged into 5 and 10 min periods and subsequently used to calculate wind  
183 direction ( $\alpha$ ) and wind speed ( $S$ ) as:

184

$$185 \quad \alpha = 180 - \text{atan2}(u, v) \quad \text{equation (1)}$$

186

$$187 \quad S = (u^2 + v^2 + w^2)^{0.5} \quad \text{equation (2)}$$

188

189 The sediment transport data were converted to total accumulation in  $\text{g m}^{-2}$  for 10  
190 and 5 min periods.

191 In order to compare the results here directly with those of Gares et al.

192 (1996) alongshore variability was quantified for each cross shore beach zone. The

193 range of variation coefficient (RVC) and the coefficient of variation (CV) were

194 calculated for the lower, mid and upper beach. The RVC is obtained by dividing the

195 average value for a set of traps by the minimum and maximum values for that set.

196 The CV is obtained by dividing the standard deviation for a set of traps by the

197 average value for that set.

198

#### 199 **4. Results and discussion**

200 Spatio-temporal patterns are evident from a time series plot for the eight-hour period.

201 A distinct clustering of sediment transport is evident in the data over the duration of

202 the event (Fig. 4). System organisation develops quite quickly after the beginning of

203 the transport event and persists, with some variation, until the end of the event.

204 Shore parallel zonation is evident for the upper and mid beach, with the lowest

205 sediment flux on the upper beach (yellow) and the high flux values for the mid beach

206 (pink). The lower beach position, however, ranges from the highest transport rates to

207 the lowest over the course of the event (blue). The spread of the data lines on the

208 plot gives a direct indication of the alongshore variation of transport. Tight clustering

209 on the upper beach (yellow lines) indicates little alongshore variability in the total

210 sediment trapped within this zone; less clustering is apparent on the mid beach (pink

211 lines); while a high degree of variability in sediment transport is evident on the lower

212 beach (blue lines).

213 A quantification of the alongshore variability for the upper, mid and lower beach sets

214 of traps is shown in Fig. 5. Although the sediment transport rate on the mid beach

215 ( $2.51 \text{ kg m}^{-1} \text{ hr}^{-1}$ ) was twice that of the upper beach ( $1.23 \text{ kg m}^{-1} \text{ hr}^{-1}$ ) the range of

216 variability is quite similar (RVC, respectively of 92–114% and 84–112%). The lower

217 beach on the other hand has a much greater range of variability (52–165%), while

218 sediment transport rates are within the range of the other zones ( $1.74 \text{ kg m}^{-1} \text{ hr}^{-1}$ ).

219 The CV results show the contrasting variability more clearly, with upper (12%) and

220 mid beach (14%) traps exhibiting similar values and the lower beach traps showing

221 much greater spatial variation (48%).

#### 222 **4.1. Cross shore patterns**

223 The patterns described above are further elucidated by mapping the transport  
224 quantities and adding a direction component. A 1 h subset of data were used from a  
225 period when airflow was directly offshore at the crest and of a sufficient speed to  
226 enable sediment transport on the beach surface. Transect B was used for this  
227 analysis as it had the most instrumentation, thereby giving the most detailed picture  
228 of the cross shore sediment transport patterns, and allowing a much clearer  
229 differentiation between zones. There are clearly identifiable trends in both magnitude  
230 of transport and the direction of movement (Fig. 6). Transport on the lower beach  
231 does not exceed  $373 \text{ g m}^{-2}$  for any 10-min period and consistently blows offshore  
232 (Zone I). The next two traps up the beach collected considerably more sediment  
233 ranging from 403 to  $997 \text{ g m}^{-2}$ , with movement fluctuating between obliquely  
234 offshore to directly offshore (Zone II). Landward of this a zone of shore parallel  
235 sediment transport is evident, with maximum transport of  $845 \text{ g m}^{-2}$  (Zone III).  
236 Transport at the dune toe diminished to range between 113 and  $667 \text{ g m}^{-2}$ , with  
237 movement consistently directed onshore (Zone IV). The sediment transport zonation  
238 across the beach remains consistent over the one hour period.

#### 239 **4.2. Alongshore patterns**

240 Alongshore patterns are assessed using the cross shore trends described in the  
241 previous section, rather than on a trap by trap basis. As the traps on Transects A, C  
242 and D had a 10 m spacing only the equivalent traps on Transect B are used for this  
243 analysis. The sediment transport on Transect A seems to follow the magnitude and  
244 direction patterns of Transect B, with the only deviation being onshore directed  
245 transport during the second 10 min period for the mid beach position (Fig. 7). The  
246 transport magnitudes of Transect C are less than that of all other lines. The transport

247 direction on the lower beach is orientated more consistently directly offshore, with  
248 the mid beach transport direction orientated alongshore to onshore in comparison to  
249 alongshore to offshore for the other mid beach traps. Line D shows the highest  
250 transport rates with consistent oblique offshore transport. Considering these data,  
251 therefore, it may be said that the cross shore zones – identified in Fig. 6 – are  
252 replicated at each position along the beach and do so consistently for the period of  
253 the transport event. Where slight alongshore deviations exist they do so in a  
254 consistent manner, suggesting there may be a fairly fixed alongshore controlling  
255 factor at play. The variability of transport direction alongshore is largest within the  
256 mid beach zone, with Transects A and C showing a majority of onshore directed  
257 transport and Transects B and D showing offshore directed transport. This also  
258 suggests the existence of preferential zones for onshore directed transport that are  
259 fairly permanent through time.

260 To assess cross and alongshore patterns further the data from 08:10 to 08:40 were  
261 binned at 5 min intervals (Fig. 8). At this time scale the the cross shore zonation for  
262 lines B and D again match those at the longer time scale, with the lower and upper  
263 beach transport patterns of lines A and C also following the trend. The mid beach  
264 traps for lines A and C exhibit highly variable transport from one period to the next.  
265 The beach sediment transport zonation at this time scale may then be described as:  
266 Zone I – lower beach, offshore directed transport of a magnitude less than the mid-  
267 beach and greater than the upper beach; Zone II – mid beach, high directional  
268 variability and highest transport rates; Zone III – upper beach, onshore directed  
269 sediment transport of realtively low magnitude. Alongshore patterns also remain  
270 fairly consistent at this time scale. However, as the time scale decreased directional

271 variability at many of the traps locations increased, especially those within the mid  
272 beach zone.

273

## 274 **5. Results and discussion**

### 275 **5.1. Alongshore sediment transport complexity**

276 The results presented here show alongshore heterogeneity in sediment transport  
277 occurs under offshore winds at this site. The pattern of variation in transport along  
278 transects spaced 30 m apart correspond, at least qualitatively, with the CFD  
279 simulation results of Jackson et al. (2011). That is, areas of higher transport  
280 (Transects A and C) interspersed alongshore with areas of lower transport  
281 (Transects B and D). Interestingly the alongshore zones persisted over the one hour  
282 period presented here – this may suggest that there is a controlling factor at play that  
283 is orientated along a cross shore plane, or that fixes the forcing airflow in that plane.  
284 So, while spatial complexity is evident in the sediment transport data, it is not chaotic  
285 and may be described as organised – possibly driven by coherent lee side airflow  
286 structures such as roller and helical vortices described by Walker and Nickling  
287 (2002). The fact that there is an oblique facet to the transport direction would be  
288 better explained if a helical vortex was present. It may be noted, however, that the  
289 alongshore component was a small fraction of the sediment being moved on the  
290 beach. If there was a more significant amount of sediment moving parallel to the  
291 dunes the alongshore variation in transport rates may not have occurred. For  
292 example, with significant shore parallel movement Transect C would be fed by  
293 Transect B and might have expected to display similar transport rates, rather than  
294 the low relative rates it actually recorded. Similarly there was a large degree of  
295 directional variability alongshore suggesting that transport was at some points

296 directed even in opposite directions within the same zone. For example, the period of  
297 time from 8:30 to 8:35 in Fig. 8 shows transport to the west in the upper beach trap  
298 (onshore) and the mid beach trap (offshore) along Transect A. Transport is aligned  
299 almost cross shore along Transect B, and it changes to the east in Transect C and  
300 D. That is to say, sediment transport was not consistently steered in one direction  
301 which suggests that there might be differentiated areas of complex airflow reversal  
302 and helical vortices deflected in different directions during perpendicular offshore  
303 winds. Although a counter point here is that sand transport may have been quite  
304 localised; relatively high mid-to-lower beach rates were not observed feeding the  
305 lower beach traps just 5 m away where the transport rate was on average 36% of the  
306 mid-to-lower beach traps on Transect B (Fig. 6). The interpretations suggested here  
307 are based on the assumption that other factors that can have a strong influence on  
308 spatio-temporal variations in sediment transport were not significant here. The  
309 shoreline during the period of time covered in Fig. 6, Fig. 7 and Fig. 8 was at least  
310 30 m apart from the last trap (low tide) and the beach surface was dry and free of  
311 debris.

## 312 **5.2. Comparison with other studies**

313 Gares et al. (1996) is the only study that had similar conditions to this one: offshore  
314 winds, a 12 m foredune and a relatively clean, flat beach surface. The positioning of  
315 their 30 m trap line is approximately comparable to the lower beach traps used in this  
316 study, while their 55 m trap line would be seaward of this position. The alongshore  
317 variability at the 30 m line (Run 10) had a range of variation from 39% to 175%  
318 (RVC; or CV 43%, calculated from values in Gares Fig. 8) compared to 52% to 165%  
319 (CV 48%) for this study. Seaward of this position the range of variation reduced  
320 considerably to 78% to 119% (RVC; CV 17%), which would be expected as the

321 topographical influence of the foredune recedes and a new internal boundary layer  
322 becomes established. In contrast, the results of this paper may be considered  
323 unexpected. The quantitative description of the airflow patterns (Delgado-Fernandez  
324 et al. companion paper) locates the mid and upper beach traps in highly turbulent  
325 areas (reversal; transition; re-attachment zones) where higher relative variations in  
326 wind speed and direction were recorded in comparison to the lower beach trap  
327 position, where a new inner boundary layer had begun to form. The alongshore  
328 variations in sediment transport do not match this pattern. The alongshore variation  
329 between traps located in the relatively more turbulent areas show low CV values of  
330 12% for the upper beach and 14% for the mid beach (and as stated above 48% for  
331 the lower beach). A possible explanation for this unexpected finding is that  
332 alongshore each set of traps – with little variability – is in the same cross shore zone,  
333 while the set of traps with high variability are in fact in different cross shore zones. In  
334 other words, all the upper beach traps are in the reversal cell, all the mid beach traps  
335 are in the transition/re-attachment zone, while for the lower beach traps some may  
336 still be in the transition/re-attachment zone, with others in the newly forming inner  
337 boundary layer. This assumes that there is a characteristic magnitude-distribution  
338 sediment transport signal for each cross shore zone.

339 Alongshore variation values reported here are comparable to other studies that have  
340 investigated variations in transport perpendicular to the airflow direction. Nordstrom  
341 et al. (2006) recorded a value of 12% variability (CV) for 3 traps on the foreshore  
342 over a distance 20 m alongshore, under offshore winds for a 2 h period (The CV  
343 value is calculated from Table 2). Over shorter scales Baas and Sherman (2006),  
344 using 35 safires over 4 m for 2 min, found CV 48% in alongshore (spanwise)  
345 variation. Also over 4 m Jackson et al. (2006) utilised five traps over a periods from

346 25 min to 1 h and recorded spatial variation perpendicular to the airflow of between  
347 33% and 91%.

348 It is significant that the results presented here show patterns evident in the sediment  
349 transport system persist over time for a relatively long record (8 h) with relatively long  
350 (10 min) averaging intervals (Fig. 4, Fig. 6, Fig. 7 and Fig. 8). Most studies on  
351 variability in sediment transport investigate the (apparent) randomness of the  
352 system, with fluctuations in the transport expected to diminish as longer averaging  
353 intervals are used. This is not the case in the results presented here, suggesting that  
354 the secondary airflow patterns (thought to be controlled by topographic variations at  
355 the fordune crest) impart a structure on the sediment transport patterns; reflected in  
356 alongshore and cross shore variability.

### 357 **5.3. Aeolian sediment transport and beach-dune dynamics**

358 Despite the alongshore variability in sediment transport patterns it is worth noting  
359 that the average rate of transport on the upper beach was  $1.23 \text{ kg m}^{-1} \text{ hr}^{-1}$  and was  
360 directed onshore, aiding in dune maintenance during offshore airflow. This finding, in  
361 addition to the alongshore variability in transport shown here, has significant  
362 implications for the modelling of beach-dune morphodynamics. In aeolian dune  
363 settings secondary airflow patterns are an inherent component. These airflows have  
364 been shown here and elsewhere to influence the sediment transport system,  
365 therefore models based on primary (regional) data alone will be fundamentally  
366 flawed. When investigating offshore airflows the use of a single cross shore transect  
367 may misrepresent the overall sediment transport budget depending on placement,  
368 even at an averaging time scale in the order of 10 min.

369

370 **6. Conclusions**

371 An understanding of secondary airflow patterns and the three dimensional nature of  
372 sediment transport is critical to understanding the morphodynamics of beach-dune  
373 systems. This study has documented various aspects of the sediment transport  
374 system on a sandy beach under offshore winds.

375 Quantifiable spatio-temporal variability in aeolian sediment transport is evident  
376 during offshore wind events. In a cross shore direction, zonation may be identified  
377 from transport magnitude and direction characteristics. These zones of sediment  
378 transport may persist over time. The cross shore trends, although consistent over  
379 time, have been shown here to vary according to their alongshore position. These  
380 results highlight the important three-dimensional nature of aeolian sediment transport  
381 in complex beach-dune systems and the need to incorporate an alongshore (or  
382 lateral) dimension in any attempts to model this environment.

383

384 **Acknowledgements**

385 We wish to thank field technicians Robert Stewart, Sam Smyth and Peter Devlin for  
386 their GPS field surveying efforts. Thanks are also extended to Colin Anderson  
387 (electronics workshop) and Nigel Macauley (mechanical workshop) whose expertise  
388 was essential in the construction of the data interface system and instrument rig,  
389 respectively. Thomas Smyth provided invaluable assistance in the field. Access to  
390 the field site was kindly provided by Defence Estates, UK. This work is funded  
391 through the UK Natural Environment Research Council grant NE/F019483/1.

501 **List of figures**

Fig. 1. Location of study site at Magilligan Strand, in Northern Ireland. The area of interest (square) covered a section of approximately 100 m alongshore.

502

Fig. 2. (A) Close up on station in position B7. Ultrasonic anemometers (UAs) were deployed at 0.5 m elevation over the beach surface and co-located with a sand trap; (B) Close up on sand trap and UA at position D3 and surface conditions during the run presented here, showing a dry, free of debris beach surface with small aeolian ripples.

503

Fig. 3. Topographic surface of the study site and experimental setup. Black dots

indicate groups of UAs, traps, and safires; triangles indicate only UAs. Instruments located at position D1 (cross) did not function properly during the period of time considered in this paper and hence have been excluded from the analysis. The beach mast contained four UAs at elevations of 0.5, 1, 2, and 4 m over the beach surface (Fig. 4B) and was located at position B2. The dune crest mast contained one UA mounted on a 6 m high mast on top of the dune crest. The horizontal distance from the dune crest mast to station B1 was approximately 30 m. The vertical axis is exaggerated.

504

Fig. 4. Sediment accumulation across the beach (10 min accumulations). Trap lines are indicated by symbol shape. Cross-shore position on the beach is indicated by color. It is evident over the course of the event that sediment transport is not uniform across the entire beach. Spatial patterns emerge soon after the beginning of the event. For example, all three upper beach traps (yellow lines) are tightly clustered throughout the time series. Another pattern is that, generally, the mid beach positions (pink line) record the highest transport rates. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

505

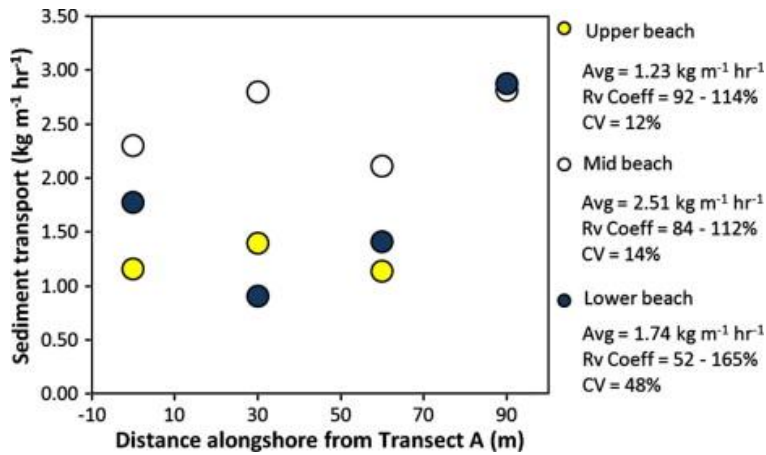

Fig. 5. Quantification of alongshore variability in sediment transport rates. Average (Avg) sediment transport rates on the mid beach were twice that of the upper beach. The range of variability (Rv Coeff) and coefficient of variation (CV) were similar and lower at the upper and mid beach but larger at the lower beach, indicating a much greater alongshore variation within this zone.

506

Fig. 6. Cross-shore zonation of sediment transport. Transport data corresponds to 10-min averages over a subset of 1 h during the transport event. Areas of the beach with consistent sediment transport rates and direction are evident in the data. Zone I – offshore movement of low magnitude. Zone II – highest transport rates on the beach with movement directly or obliquely offshore. Zone III – shore parallel transport of intermediate magnitude. Zone IV – low rates of obliquely onshore sediment transport.

507

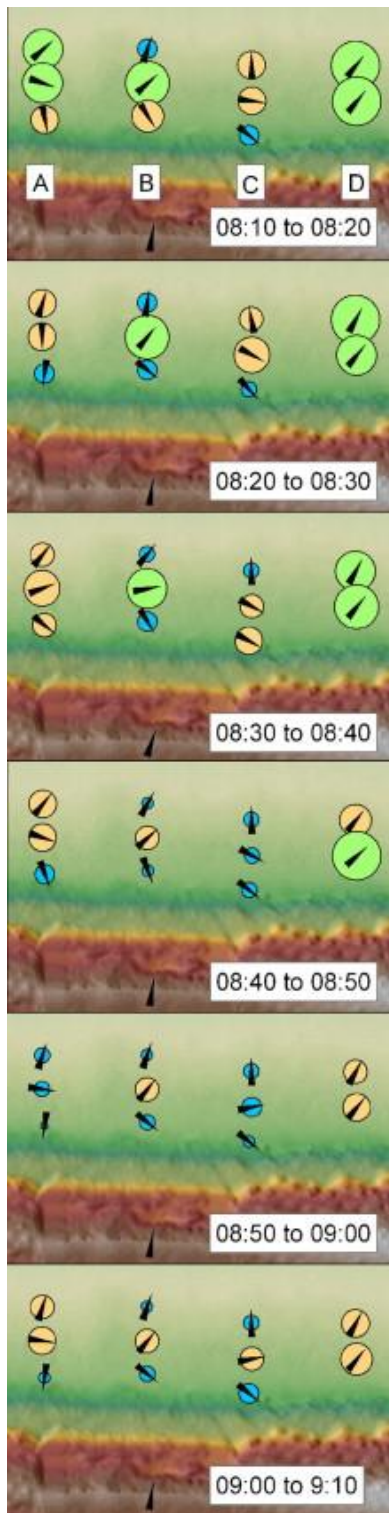

Fig. 7. Alongshore variations in cross-shore zonation of sediment transport.

Deviation in the cross-shore trends identified for line B are evident alongshore, this may be expected – the striking aspect is the cross-shore trends for each line show a considerable degree of consistency (in transport direction and relative magnitude) for

the hour of data presented here.

Fig. 8. Five-min intervals of sediment transport. Cross-and alongshore patterns identified at the longer timescale remain identifiable at this scale, suggesting complex yet semi-fixed controlling factors are present. The decrease in time scale increased the complexity of transport patterns, suggesting that the wind was steered in opposite directions alongshore within the same zone during certain time intervals (e.g., at the upper beach from 8:35 to 8:40).
