Keywords:	Theory of mind, Executive Function, Self/other interference, Path analysis

Dear Editors,

Please accept this revised paper '*Does interference between self and other perspectives in Theory of Mind Tasks reflect a common underlying process? Evidence from individual differences in theory of mind and inhibitory control*', Manuscript ID PBR-BR-19-078, for consideration at publication at Psychonomic Bulletin & Review, submitted as an original article.

Despite the vast literature on theory of mind (the ability to understand other agents have different beliefs, desires and knowledge to oneself), the nature and origin of interference effects seen between the 'self' and 'other' perspectives in ToM tasks have not been examined in terms of individual differences. The current study addresses two fundamental questions within the theory of mind literature: are there systematic individual differences in self-other interference, and are these differences due to individual differences in executive function? The study comprised a large-scale path analysis model examining the relationship between performance on inhibitory control and two theory of mind tasks that involve dealing with interference between self and other perspectives. Results suggest that self/other interference effects in the two ToM tasks were dissociable, and related to different tests of inhibitory control. We conclude that while self/other interference is a key part of ToM tasks, it may not be the only limiting step for healthy adults' performance on typical tasks.

9 Editor comments

10
11 “your 'theory of mind' tasks may not actually require representing others' mental states. If this
12 is the case, your data may not allow us to draw conclusions about ToM in general, but just
13 about these two tasks; and an alternative interpretation of your data would be that these two
14 tasks are themselves measuring domain-general inhibition and not ToM. I'd like to see a
15 robust rebuttal of this interpretation.”
16
17

18 ***We have added a substantial new section to the discussion to address this concern.
19
20

21 Please expand on the implications of the finding that the general inhibition tasks don't
22 correlate particularly highly with each other; The reliability was poor for 'ambiguous errors'
23 in the director task – please discuss this in your comments on reliability in the final sections
24 of the manuscript; Please include a statement regarding ethical approval.
25
26

27
28 ***Thanks for highlighting these. We have added a line re. low reliabilities to the Limitations
29 in ToM measures section: **we note that while task reliabilities were generally high (< .7)**
30 **the reliability for ambiguous errors in the Director task was .59.** The low correlations
31 between the inhibitory control tasks are common in the literature (e.g. Friedman & Miyake,
32 2004), potentially due to task impurity issues. We have added a line to reflect this to the Data
33 screening section. We have also added a line to the participants section regarding ethical
34 approval: **Ethical approval was gained from the departmental ethics committee.**

41

42 Comments to the Author

43 This paper involves two assessments of Theory of Mind abilities – visual perspective taking
44 Level 1 and a referential communication task, the 'Director' task – along with four different
45 measures of inhibitory control, aiming to establish (1) whether self/other interference effects
46 are seen to the same extent across different tasks, (2) how inhibition predicts ToM task
47 performance, and (3) whether the inhibition and ToM relationship varies across tasks. The
48 study utilized a good sample size of 142 participants, and used path analysis to examine
49 relationships between outcomes. Results showed a dissociable self/other interference effect
50 across the two ToM measures; further, path analysis showed that each of the ToM task
51 interference effects were predicted by different inhibitory control tasks. The authors conclude
52 that self/other interference is not a unitary construct, varying across different task demands.
53
54

55
56 This paper is well-written and thorough, and was enjoyable to read, addressing a key research
57 area in ToM literature (individual differences in ToM and executive control). The study
58 involved a large subject number, and used a number of different tasks to assess both ToM and
59 EF, allowing subtle differences between tasks and relationships across tasks to be assessed. I
60

1
2
3 have some minor clarification points as detailed below, but overall was impressed with the
4 study.
5

6 Introduction:
7

8
9 Page 4, line 50-53: The authors review here prior literature that has suggested training
10 participants to inhibit automatic imitation led to improved performance on a test of ToM,
11 whereas generic inhibition training did not. This could do with a bit more explanation to
12 make the prior findings clearer, including why decreased imitation would lead to ToM
13 improvement and how this relates to the current study.
14

15
16 ***We have added lines (in bold) to clarify why this effect may have occurred:

17 “Santiesteban, White, Cook, Gilbert, Heyes and Bird (2012) found that training participants
18 to inhibit automatic imitation improved performance on a test that required participants to use
19 their ToM (the Director Task; Keysar, Lin & Barr, 2003), whereas training generic inhibition
20 did not, suggesting that inhibition of automatic imitation and **ToM rely on control over**
21 **representations related to self and other, and these control processes are not the same as**
22 **those involved in conventional “inhibition” tasks.”**
23

24
25 With regard to the relationship to the current study, we go on to state that such findings
26 (along with neuroscience findings, e.g. Bardi, Six & Brass, 2017; Wagner, Maril, Bjork &
27 Schacter, 2001) suggest that self-other control is a more domain-specific process as “**generic**
28 **inhibition training did not improve ToM performance; though see a recent meta-**
29 **analysis by Darda and Ramsey (2019))”, and that this leads to our “prediction that there**
30 **will be individual differences in self-other control across different ToM tasks, and that these**
31 **should not be related to individual differences in executive function.”**
32
33

34
35 Page 4, line 29-33: this is a personal preference, but I would avoid starting a sentence with
36 the word ‘and’ – this makes the paragraph a bit jumpy.
37

38
39 ***So edited – thanks for spotting this.
40

41 Appendix A (Individual Task Results):
42

43 Shape-Matching Task (and others): the authors state that ‘Response time values that were
44 more than three standard deviations away from the condition mean for a participant were
45 replaced by the cut-off value (of three standard deviations from the condition mean)’. Could
46 the authors please comment on why this approach was taken? It is not clear why these values
47 were not removed as outliers, rather than replaced. Additionally, please include information
48 about how many data points were required to be changed/how many exceeded this cut off.
49

50
51 ***We didn’t remove the outliers as we followed the recommended data screening procedure
52 of Friedman and Miyake (2004) and Oberauer (2005) in order to retain as many data points as
53 possible, and also to reduce the effect of any extreme response times on the mean.
54
55

56 For those measures that used error rates (Go / No-Go (picture) and Go / No-Go tasks), no
57 outliers were removed or replaced. For the Shape-matching task 1.41% of trials were
58 replaced. For the Stop-Signal task, no initial data points were removed or replaced, but two
59 participant SSRT values were replaced as per Tabachnick and Fidell (2001) due to an
60

1
2
3 extremely non-normal distribution. For the L1-VPT task, only matching trials were analysed.
4 Of these 1.41% were incorrect responses, 2.04% had response times more than 2.5 SDs from
5 the mean, and 0.47% were response omissions, totalling 3.92%. The Director Task replaced
6 0.48% of trials.
7

8
9 Lines covering the above have been added to section A3 of the new Appendix A (executive
10 task details).
11

12 A minor point, but why for inhibitory control tasks were responses removed if over 3
13 standard deviations from the mean, but for the L1 VPT task 2.5 standard deviations was used
14 as criteria?
15

16
17 ***We followed the procedures most commonly employed in the published literature for the
18 L1 VPT task (Qureshi et al., 2010) and for the various inhibitory control tasks, and have
19 added a footnote to reflect this.
20

21 Discussion:

22
23 Page 21 – Lines 18-36: This paragraph needs to be more fully explained/contain further
24 information to make argument clearer.
25

26
27 ***We have edited this paragraph to improve the clarity of the argument, we hope that this is
28 now clearer.
29

30 Reviewer: 2
31

32
33 Comments to the Author

34 The paper investigates individual differences in Theory of Mind performance and the
35 relationship between self-other interference and inhibitory control. The research question is
36 relevant and the manuscript has certainly the potential to provide an important contribution to
37 the literature of the field. However, I list below some issues/questions that should be
38 addressed to improve the quality of the manuscript.
39

- 40
41 1. A number of “executive control” tasks have been included in the study (some of which
42 are not reported in the manuscript). I assume the authors meant to measure different
43 aspects of inhibitory control but I have the impression that the theoretical motivation
44 behind task selection is missing.
45

46
47 It is also not clear what were the specific predictions with respect to correlations with
48 individual tasks. In effect, results show that the two perspective taking tasks correlate
49 with different measures of executive control (i.e., different tasks). The interpretation of
50 this outcome seems to be challenging, but I think the authors should try to elaborate a bit
51 more on that.
52

53
54 ***We have added a short section on executive task selection on p9 of the main manuscript
55 and in Appendix A included a more extensive discussion of the rationale for task selection,
56 analysis, and predictions for relationships among tasks.
57
58
59
60

2. *The sample size has been selected without an appropriate power analysis. A power analysis should be performed to determine the optimal sample for the study.*

***This was an omission on our part, thank you for pointing it out. At the time of data collection, the rule of thumb sample size (Kline, 2005) was used which suggests a 10:1 ratio for free parameters as a realistic figure. This gives sample sizes of 180 for the initial model, 60 for the second model and 80 for the final model. He also suggests that a sample size of between 100 – 200 can be considered a medium sample size.

Preacher and Coffman (2006) provide a sample size and power analysis calculator based on RMSEA values. Taking α as .05, $df = 20$ (final model), and $n = 142$, and setting the null RMSE value as .08 (cut-off for a poor fitting model; Kenny, 2015) and the alternative RMSEA value as .00 (final model), this gives us a power of .67 to detect whether this is a poor fitting model.

The same calculator suggests with null RMSEA = .01 (excellent fit), alternative RMSEA as .08 (mediocre fit) and an observed power of .8, the sample size should be 169. Therefore we believe that considering the experimental nature of the study, the sample size is sufficient for the model, which is supported by the bootstrapping estimates. Indeed, changing the mediocre fit cut-off RMSEA value to .10 (as per Kline, 2005) changes the observed power to .92, and the recommended sample size to 107.

We have added the following after Table 4:

A power analysis was conducted on the final model fit values and sample size using Preacher and Coffman's (2006) power and sample size calculator for RMSEA. This suggests that the current sample size has a power of .92 to detect whether this was a poor fitting model¹. Testing whether the sample size was sufficient for the final model showed that an ideal sample size should be 107 (with .10 as the RMSEA value for a poor fit; Kenny, 2014²). Kline (2005) suggests a 10:1 ratio for free parameters as a realistic figure, which gives an estimated sample size of 80 for the final model. The current sample size is appropriate for the current analyses.

Kenny, D. A. (2014, January 12). Structural Equation Modelling. Retrieved June 11, 2019, from <http://davidakenny.net/cm/causalm.htm>

3. It is not clear to me why the two perspective-taking tasks were chosen over other measures of self-other control. Moreover, aren't those two tasks typically considered to measure perspective taking, and not ToM tasks?

***We thank the reviewer for encouraging us to make our reasoning apparent here, but respectfully disagree with the suggestion that visual perspective-taking is distinct from ToM.

¹ Observed power = .8, $df = 20$, $n = 142$, null RMSEA = .01 (excellent fit), alternative RMSEA = .00 (final model value).

² Observed power = .8, $df = 20$, null RMSEA = .01, alternative RMSEA = .10

1
2
3 In support of our position, we note that visual perspective-taking is widely seen as a
4 component of the development of ToM in children, and features in much contemporary
5 discussion of the cognitive basis of ToM in adults. Our choice of these tasks was further
6 influenced by the fact that they are relatively unusual in having been analysed into
7 component processes to which inhibitory control may make distinctive contributions. This
8 contrasts with the majority of ToM “measures” which are often quite opaque with respect to
9 their underlying functional processes. On p10 we now include a paragraph explaining this
10 rationale.
11
12
13
14

15 4. Two different versions of a go/no-go task were included. How the distinction between
16 letter and image-based task would be relevant to the goal of the study?
17

18 ***The Go / No-Go (picture) based task required an additional step of processing (the
19 identification of the image as being a bird or mammal), followed by the response
20 inhibition/selection required to choose whether to respond or not, based on the phonological
21 or orthographical information (did the name begin with a vowel or consonant). This
22 represented another variation of task that requires inhibition, which also required an
23 additional step of response selection, resulting in more individual variability in inhibition
24 being captured. We have detailed this in section A2 of Appendix A (executive task details).
25
26
27
28

29 5. The interference effect for the shape-matching task was calculated by using only two
30 of the four task conditions: the no-match distractor and the match no-distractor condition.
31 This choice seems arbitrary to me (and I find the explanation provided in the appendix not
32 completely convincing). I think the authors should rather consider the difference between the
33 two distractor present conditions and the two distractor absent conditions (distractor present
34 match + distractor present no-match)/2 – (distractor absent match + distractor absent no-
35 match)/2.
36
37

38 ***Again, thank you for this suggestion. We agree, and have reanalysed the data accordingly
39 with the suggested difference scores. The resulting model shows the same relationships with
40 the ToM tasks, but no correlation between the shape-matching and stop-signal tasks.
41
42

43 6. About the shape-matching task, it was reported in the appendix: “there was an
44 interaction between distraction and matching as can be noted in Figure A3”. However,
45 perhaps because the scale of the figure, it is not clear what the interaction entails. Please
46 adapt the graph accordingly.
47

48 ***We have adjusted the y-axis on 480ms rather than 0ms, so the interaction caused by the
49 longer response times to Target MisMatch compared to TargetMatch when the distractor was
50 present is more visible.
51
52
53

54 7. The shape-matching task was an adapted version of a task developed by DeSchepper
55 and Trieseman, 1996. How was the task modified with respect to the original version and
56 why?
57

58 ***We reduced the number of trials to 112 across 4 blocks rather than 200. The task was also
59 simplified to measure resistance to distracters and resistance to inappropriate responses,
60

1
2
3 rather than negative priming as in DeSchepper and Treisman (1996). This was done by
4 presenting the distracter shapes at the same time as target shapes in the experimental trials,
5 requiring participants to actively keep the distracters from interfering with processing of the
6 target shapes (Endo, Saiki & Sato, 2001).
7

8 We have added the following to section A2 of Appendix A (executive task details):
9

10 **The task was simplified to measure resistance to distracters and resistance to**
11 **inappropriate responses, rather than negative priming as in DeSchepper and Treisman**
12 **(1996). This was done by presenting the distracter shapes at the same time as target**
13 **shapes in the experimental trials, requiring participants to actively keep the distracters**
14 **from interfering with processing of the target shapes (Endo, Saiki & Sato, 2001).**
15
16
17
18

19 Endo, N., Saiki, J. & Saito, H. (2001). Determinants of occurrence of negative priming for
20 novel shapes with matching paradigm. *Japanese Journal of Psychology*, 72 (3), 204 – 212
21
22
23

24 8. The method section lacks important details about the visual stimuli (stimulus size,
25 duration...), responses recording, number of trials....etc...
26
27

28 ***We have added a section for this (A2) in Appendix A (executive task details).
29
30

31 9. The path analysis, as well as the results, need to be described in more details in the
32 main text, especially for the reader who is not familiar with this kind of approach, and not
33 only in the appendix.
34
35

36 ***Thank you for this advice. We have added a brief summary of the aim of path analysis to
37 the start of the Models sub-section (page 14; "Path analysis aims to arrive at the most
38 parsimonious model that explains the underlying data and does not significantly differ from
39 it. Increasing the number of parameters in a model tends to improve fit, but necessarily
40 decreases parsimony. The best model optimises fit and parsimony." We have also given more
41 detail on each model in the main results (while keeping the full tables/figures in Appendix B
42 for brevity), including information on model comparisons (pages 14 – 15).
43
44
45

46 10. I am wondering whether having a fixed task order was the right choice. As tasks are
47 supposed to measure similar constructs, it is plausible that performance in one task has an
48 influence on the performance of subsequent tasks. Counterbalancing the task order should
49 have controlled this.
50

51 ***This is a very good point, and one we did not fully explain. We decided on a fixed order
52 because this is widely-acknowledged to be the most powerful design in individual differences
53 research (e.g. Carlson & Moses, 2001; Carlson et al., 2004; Friedman & Miyake, 2004;
54 Miyake et al., 2000; Miyake, Friedman, Rettinger, Shah & Hegarty, 2001). While the patterns
55 of correlation between tasks should be the same for any task order, variation in order within a
56 sample introduces irrelevant variance that can obscure correlations. To illustrate, consider
57 tasks A and B that are highly correlated, such that the true rank order of participants'
58 performance is the same on A and B. Now suppose A and B are presented in a battery on
59
60

1
2
3 which participant tiredness naturally leads to decreasing performance over time. In a fixed
4 order design in which task A always occurs before B, performance on B will be
5 underestimated compared with A, but the true rank order of participants on each task will be
6 preserved. In contrast, a design that varies task order makes it possible that a participants'
7 rank on any one task may shift above or below that of other participants on that task just
8 because they happened to complete the tasks in different orders (and so varied in levels of
9 tiredness). This reduces the power for detecting the true association that exists between the
10 tasks.
11
12

13
14 Fixing the task order avoids this problem, but we note that a given task order may result such
15 a degree of tiredness that task performance can no longer be assessed reliably. To check
16 whether the performance on tasks influenced one another, perhaps due to there being a finite
17 resource for executive components (Muraven & Baumeister, 2000), participants completed
18 the Go / No-Go task at the start and end of each session, and results compared. These showed
19 no difference, suggesting that fatigue and/or influence of similar tasks on performance did not
20 occur.
21

22
23 We have added the following to the Task order section: **This was done because a fixed task
24 order is optimal for detecting correlations** (e.g. Carlson & Moses, 2001; Carlson et al.,
25 2004; Friedman & Miyake, 2004; Miyake et al., 2000; Miyake, Friedman, Rettinger, Shah &
26 Hegarty, 2001). **To check whether the performance on tasks influenced one another,
27 perhaps due to there being a finite resource for executive components (Muraven &
28 Baumeister, 2000), participants completed the Go / No-Go task at the start and end of
29 each session, and results compared. These showed no difference, suggesting that fatigue
30 and/or influence of similar tasks on performance did not occur.**
31
32

33
34 11. The Director task is a typical explicit task, because subjects are always instructed to
35 take the perspective of the avatar. The L1 VPT task is, on the other hand, at least partially
36 implicit (the effect of the avatar's perspective is automatic in "self" trials). A possible
37 dissociation between implicit and explicit ToM is a matter of intense debate. I wonder
38 whether one should not consider the interference effect in "self" and "other" trials separately.
39 Possible implicit/explicit dissociation might come to help in the interpretation of the path
40 analysis outcome.
41
42

43
44 ***Thank you for this suggestion. We certainly recognise this interesting issue. Our analysis
45 strategy derives from the challenges in deriving maximally informative dependent variables
46 from tasks that obviously involve multiple processes. To illustrate, the magnitude of the
47 altercentric interference effect in a Self trial is likely to depend on BOTH the propensity for a
48 participant to process the avatar's perspective (or the weight or salience they accord that
49 perspective), AND the participants' capacity to give a controlled response in the face of
50 interference from the avatar's perspective. With appropriate changes made, the same analysis
51 applies to egocentric interference on Other trials. [Note also, an analogous analysis would
52 apply to alternative interpretations of this effect in terms of spatial cueing.] Following
53 Bukowski & Samson, our strategy is to orthogonalise these factors, to derive indices of focus
54 (weighting of self vs other) and conflict (ability to resolve self-other interference). We think
55 this is maximally informative, but we agree that, since much of the published literature has
56 looked separately at interference on Self and Other trials, it is also informative to look at
57 these trials separately. Therefore in Appendix C we now present models using interference
58 measures (from self perspective; egocentric interference, and other perspective; altercentric
59
60

1
2
3 interference). Results show that interference from the self perspective is related to the SST,
4 but that interference from the other perspective is not related to any of the executive tasks.
5 We have made a note to this effect in the result section.
6

Abstract

Theory of mind (ToM), the ability to understand other agents have different beliefs, desires and knowledge to oneself, has been extensively researched. Theory of mind tasks involve participants dealing with interference between their self-perspective and another agents perspective, and this interference has been related to executive function, particularly inhibitory control. The current study assessed whether there are individual differences in self/other interference, and whether these effects are due to individual differences in executive function. 142 participants completed two theory of mind tasks (the Director Task and a level one visual perspective-taking task), which both involve self-other interference, and a battery of inhibitory control tasks. The relationships between the tasks were examined using path analysis. Results showed that the self/other interference effects of the two ToM tasks were dissociable, with individual differences in performance on the ToM tasks being unrelated and performance in each predicted by different inhibitory control tasks. We suggest that self/other differences are part of the nature of theory of mind tasks, but self/other interference is not a unitary construct. Instead, self/other differences result in interference effects in a variety of ways and at different stages of processing, and these effects may not be a major limiting step for adults' performance on typical ToM tasks. Further work is needed to assess other factors that may limit adults' ToM performance and hence explain individual differences in social ability.

Key words: Theory of mind; Executive Function; Self/other interference; Path analysis

Introduction

Theory of mind (ToM) has been defined as the ability to understand that other agents have different beliefs, desires and knowledge to oneself (Premack & Woodruff, 1978). While neurotypical adults clearly understand the principle that other people may have a different perspective to themselves (perhaps unlike children e.g. Perner & Ruffman, 2005; though see Onishi & Baillargeon, 2005), they nonetheless are prone to systematic difficulties arising from conflict between their own perspective (self-perspective) and another's. Most notably, adult participants show "egocentrism" across a very wide range of tasks, whereby their judgment of what someone else sees, thinks, or wants is slower or more error-prone when this differs from what participants themselves see, think, or want (Royzman, Cassidy & Baron, 2003). Understanding the nature and origin of such interference effects is critical for theories about the functional bases of ToM, and understanding variability in these effects between individuals holds out the promise of helping explain why some people are more socially able than others (e.g., Apperly, 2012). Despite the recent proliferation of tasks available for studying ToM in adults, little is yet known about individual differences in ToM performance. Therefore the present study addressed two fundamental questions: Are there systematic individual differences in self-other interference; and are these effects due to individual differences in executive functions?

Studies of ToM in adults have focussed on both typical and atypical participants. Specifically, research has examined healthy young adults (e.g., Bradford, Jentsch & Gomes, 2015; Qureshi & Monk, 2018), and older adults (Bernstein, Thornton & Sommerville, 2011), patients with brain injury (e.g., Apperly, Samson & Humphreys, 2005; Stone, Baron-Cohen & Knight, 1998), those with Autism Spectrum Disorder (e.g., Baron-Cohen, Jolliffe, Mortimore & Robertson, 1997), psychopathy (e.g., Lockwood, Bird, Bridge & Viding, 2013) and dementia (e.g., Le Bouc, Lenfant, Delbeuck, Ravasi, Lebert, Semah & Pasquier, 2012).

1
2
3 Research in this area has also utilised a variety of different methodologies including dual-
4
5 tasking (e.g., Bull, Phillips & Conway, 2008; Qureshi, Apperly & Samson, 2010), brain
6
7 stimulation (e.g., Kalbe et al., 2010), neuro-imaging (e.g., Reiniers, Völlm, Elliott &
8
9 Corcoran, 2014) and individual differences (Ryskin, Benjamin, Tullis & Brown-Schmidt,
10
11 2015). Nevertheless, a unifying feature of the tasks is that they generate a difference between
12
13 the perspective of the participant (self-perspective) and that of the target (other-perspective),
14
15 with the resulting interference between the self and other perspectives requiring resolution in
16
17 order to judge what the other thinks, sees, or feels. This gives rise to the widely-reported
18
19 phenomenon of “egocentric bias” towards the participant’s own perspective, which is almost
20
21 universally observed in studies of ToM (Royzman, Cassidy & Baron, 2003; Wellman, 2014).
22
23 However, it is currently unclear whether self-other interference results from the same
24
25 underlying functional process on different tasks. While everyday experience lends credibility
26
27 to the hypothesis that some individuals are consistently more egocentric than others, few
28
29 studies have examined whether this is the case.
30
31
32
33
34
35

36 One leading hypothesis is that interference between self and other perspectives in
37
38 ToM tasks forms part of a broader domain of phenomena in which representations relating to
39
40 self and other must be controlled (e.g., Cook, 2014). For example, observing another’s action
41
42 generates a tendency for “automatic imitation” of the action by one’s self, which must be
43
44 controlled if it is not the action required by the task or ongoing activity (Brass, Bekkering,
45
46 Wohlschläger & Prinz, 2000). Santiesteban, White, Cook, Gilbert, Heyes and Bird (2012)
47
48 found that training participants to inhibit automatic imitation improved performance on a test
49
50 that required participants to use their ToM (the Director Task; Keysar, Lin & Barr, 2003),
51
52 whereas training generic inhibition did not, suggesting that inhibition of automatic imitation
53
54 and ToM rely on control over representations related to self and other, and these control
55
56 processes are not the same as those involved in conventional “inhibition” tasks. Moreover,
57
58
59
60

1
2
3 self-other control appears to depend upon regions of medial prefrontal cortex and temporo-
4
5 parietal cortex that are distinct from more lateral prefrontal brain regions frequently
6
7 implicated in analogous non-social executive control (Bardi, Six & Brass, 2017; Brass, Ruby
8
9 & Spengler, 2009; Brass, Derrfuss & von Cramon, 2004; Wagner, Maril, Bjork & Schacter,
10
11 2001). Such findings suggest that the same self-other control process may underlie both
12
13 imitation inhibition and perspective-taking, and that self-other control processes are in an
14
15 important sense “domain-specific”, and distinct from domain-general executive functions (as
16
17 generic inhibition training did not improve ToM performance; though see a recent meta-
18
19 analysis by Darda and Ramsey (2019)). This clearly leads to the prediction that there will be
20
21 reliable individual differences in self-other control across different ToM tasks, and that these
22
23 should not be related to individual differences in generic executive function.
24
25
26
27
28

29
30 However, there is also substantial evidence suggesting that domain-general executive
31
32 function is involved in ToM, and in particular in self-other control. Research on both children
33
34 (Carlson & Moses, 2001; Carlson, Moses & Breton, 2002, Carlson, Moses & Claxton, 2004)
35
36 and adults (German & Hehman, 2006; Bradford, Jentzsch & Gomez, 2015) has shown a
37
38 relationship between EF and ToM, and this has been suggested to explain deficits and
39
40 impairments in ToM performance (Bull et al., 2008; McKinnon & Moscovitch, 2007). While
41
42 there is some evidence of a role for working memory (e.g., Qureshi & Monk, 2018; Ryskin et
43
44 al., 2015), inhibitory control has been frequently linked with enabling the participant to
45
46 control interference between self and other perspectives in order to select the one required by
47
48 the task. For example Qureshi, Apperly and Samson (2010) found that a secondary task
49
50 taxing inhibitory control disproportionately impaired perspective-taking on trials involving
51
52 self-other conflict compared with trials without conflict (see also Todd, Cameron & Simpson,
53
54 2017). Moreover, there is converging evidence from research using EEG, fMRI,
55
56
57
58
59
60 neuropsychological studies of patients with brain injury, as well as TMS, that the inferior

1
2
3 frontal gyrus – a brain region frequently implicated in generic inhibitory control – is involved
4
5 in managing self-other conflict when it arises during visual perspective-taking (e.g.,
6
7 McCleery et al., 2011; Ramsey et al., 20013) and reasoning about false beliefs (e.g.,
8
9 Hartwright et al., 2012, 2016; Samson et al., 2005, 2016). This evidence leads to the
10
11 prediction that individual differences in self-other control on ToM tasks could be related to
12
13 individual differences in generic executive control (in particular inhibitory control). This
14
15 evidence would also be consistent with reliable correlations in self-other control across
16
17 different ToM tasks, but such relationships should be mediated by individual differences in
18
19 domain-general executive control, rather than by any specific process for self-other control.
20
21 Importantly, this way of thinking about ToM tasks also allows for the possibility that though
22
23 self-other control is typically assumed to be a coherent process common to all ToM tasks,
24
25 egocentrism and other self/other interference effects are instead a “family” of phenomena that
26
27 can arise in different ways across different tasks or situations. On such an account self-other
28
29 interference effects may not correlate across different ToM tasks but would correlate with
30
31 executive function tasks. The pattern of those correlations would then depend upon when and
32
33 how self-other interference arises during the ToM task, and the particular executive demands
34
35 that arose as a result.
36
37
38
39
40
41
42

43 In the largest individual differences study of ToM to date, the current study therefore
44
45 examines the relationship between performance on inhibitory control tasks and two ToM
46
47 tasks that both involve dealing with interference between self and other perspectives. The two
48
49 ToM tasks used were a Level 1 Visual Perspective Taking (L1-VPT) Task (Samson et
50
51 al.,2010) and the Director Task (based on the experiment of Keysar, Lin & Barr, 2003).
52
53
54

55 The L1-VPT Task requires participants to judge how many dots appear on the walls
56
57 of a room either from their own perspective or from the perspective of an avatar in the room.
58
59
60

1
2
3 This involves control processes relating to the ability to regulate the choice of responses (e.g.,
4 perspective selection) as well as more automatic processes which are associated with the
5
6 calculation of an ‘other’ perspective (see Qureshi, Apperly & Samson, 2010). In terms of
7
8 individual differences, this task has recently been used to create separate measures of
9
10 “conflict” (relating to the interference between self and other perspectives) and “focus”
11
12 (relative ease of judgements relating to self versus other; Bukowski & Samson, 2017). These
13
14 measures allow the separation of two components that may contribute to successful
15
16 perspective-taking, but which are confounded in standard measures of speed or accuracy of
17
18 judging the perspectives of others.
19
20
21
22
23
24

25 The Director task involves the participant following the instructions of a director who
26
27 has a spatially opposite perspective to their own, and moving objects that are mutually visible
28
29 (target objects) while avoiding objects visible only to the participant (competitor objects;
30
31 Apperly et al., 2010). This task therefore also requires participants to resolve interference
32
33 between self and other perspectives, though errors appear to arise not from difficulty with
34
35 taking the director’s perspective, but with integrating this perspective with the director’s
36
37 message in order to constrain reference (Barr, 2008).
38
39
40
41

42 Path analyses were used to model the relationship between four inhibitory control
43
44 tasks and measures of ToM tasks. Given the near ubiquity of egocentric effects and other
45
46 self/other interference effects, it is plausible that these effects reflect a common underlying
47
48 process, with shared variance such that someone who shows (say) high self/other interference
49
50 on one task will also show high interference on another. Prediction 1: This observation
51
52 predicts a significant path between measures of self/other interference in the different ToM
53
54 tasks; an important prediction that has received little empirical attention to date (see Ryskin et
55
56 al., 2015 for an exception in the context of perspective-taking during communication).
57
58
59
60

1
2
3 Prediction 2: If inhibitory control is required for dealing with self/other perspective
4
5 interference and egocentrism (failures to inhibit self-perspective), paths would be expected
6
7 between inhibitory control and ToM. Prediction 3: If predictions 1 and 2 are both supported
8
9 then the domain-general account of self-other control predicts that the relationships between
10
11 self-other interference on different ToM tasks will be fully mediated by inhibitory control,
12
13 whereas the domain-specific account of self-other control predicts that it will not be
14
15 mediated. Prediction 4: If only Prediction 2 is supported and if self-other interference arises
16
17 in different ways for different ToM tasks, then self-other interference on different ToM tasks
18
19 might correlate with different inhibition tasks.
20
21
22
23
24
25
26
27

28 **Method**

29 *Participants*

30
31
32 One hundred and fifty-four university student participants took part in the study for course
33
34 credits or cash payment. Participant ages ranged from 18 to 44 ($M = 21.8$, $SD = 4.4$), with 31
35
36 males and seven who were left-handed (two of whom used their right hand normally). Ethical
37
38 approval was gained from the departmental ethics committee.
39
40
41
42
43
44

45 *Materials*

46
47 All the experiments were designed and presented on a 15-inch Samsung SyncMaster 793s
48
49 monitor connected to a 3.00 GHz Pentium based desktop PC using EPrime 1.1 (Schneider,
50
51 Eschmann & Zuccolotto, 2002), apart from the visual perspective task which was presented
52
53 using DMDX (Forster & Forster, 2003). A standard 102 keyboard was used for responses.
54
55
56
57

58 *Inhibitory Control tasks*

59
60

1
2
3 Based on Friedman and Miyake (2004), we chose tasks that required inhibition at different
4 stages of processing, including resistance to distracting stimuli, resistance to distracting
5 information held in working memory, and resistance to selecting a prepotent but incorrect
6 response. Further details on the choice of tasks (A1), task methodology (A2) and all
7 individual task results (A3) are shown in Appendix A, where two further IC tasks are
8 described, a Simon task and a Cued Recall task¹. These were not included in the final
9 analyses due to having no relationship with any of the other tasks in the model and low
10 reliability respectively.
11
12
13
14
15
16
17
18
19
20
21

22 *Shape-Matching*

23
24
25 Participants were shown a green target shape and a white shape (see. DeSchepper &
26 Trieseman, 1996). On 50% of trials there was a red distracter shape placed over the target.
27
28 Participants were asked to decide if the target matched the white shape. The dependent
29 variable for the path analysis model was the difference in response times (to correct trials)
30 between the two distracter present conditions and the two distracter absent conditions
31 $((\text{distracter present match} + \text{distracter present no-match})/2 - (\text{distracter absent match} +$
32 $\text{distracter absent no-match})/2)$.
33
34
35
36
37
38
39
40
41
42

43 *Stop-signal*

44
45 Participants were presented with stimuli (“O” or “X”) and instructed to respond by pressing
46 the same key on the keyboard (Go trials: 75% of all trials), apart from Stop trials (25%) -
47 trials in which a tone was heard at a set delay (stop-signal delay; SSD) after presentation of
48 the stimulus. The SSD followed a dynamic tracking procedure starting at 250ms, and
49 increased by 50ms on a correct (non-)response, and decreased by 50ms on an incorrect
50
51
52
53
54
55
56

57
58 ¹ The original design selected two sets of 3 inhibitory control tasks as indicators for two latent variables for
59 cognitive and response inhibition. However, the covariance structure did not support this theoretically motivated
60 distinction between latent variables, and so tasks with adequate measurement properties were instead utilised as
individual predictors.

1
2
3 response (to stop trials). Stop-signal reaction time (SSRT) was calculated as mean Go RT –
4
5 mean Stop RT.
6
7

8 *Go/No-Go (letter-based)*

9

10
11 Participants were shown serially presented letters on-screen that they were required to
12
13 respond to by pressing the spacebar (go trials) (Wager et al., 2005). This was the requirement
14
15 for all letters except for the letter K (no go trial; 13.85% of all trials). The dependent variable
16
17 was the False Alarm Rate (FAR) for No-Go trials.
18
19

20 *Go/No-Go (image-based)*

21

22
23 This task was based on the study of Schmitt et al. (2000) and required a two-step process to
24
25 respond correctly: the initial step was based on semantic information (image of either a bird
26
27 or a mammal) and the go / no go step on phonological or orthographical information (Go trial
28
29 = initial letter was a consonant, No Go trial = initial letter was a vowel; van Turenout et al.,
30
31 1997). The measure taken was the FAR to no go trials.
32
33
34
35
36
37
38
39

40 **ToM tasks**

41

42
43 Visual perspective-taking is widely regarded as an important component of children's
44
45 developing ToM (e.g., Wellman, 2014) and of the mature ToM abilities of adults (e.g.,
46
47 Apperly, 2010). We selected two tasks that have been widely-used in laboratory
48
49 investigations of ToM in adults, and for which there were task analyses of component
50
51 processes to which inhibition might contribute: the L1-VPT task requires calculation of
52
53 another person's visual perspective; the Director Task requires calculation of another
54
55 person's perspective, plus the use of this information to interpret their instructions. In the
56
57
58
59
60

1
2
3 discussion we evaluate the implications for the present work of alternative interpretations of
4 these tasks.
5
6

7 8 *LI-VPT task* 9

10
11 The visual perspective-taking task used the stimuli and procedure of Experiment 1 in Samson
12 et al. (2010). The stimuli consisted of a picture showing a lateral view into a room with the
13 left, back and right walls visible and with red dots displayed on one or two walls (stimuli
14 were created using the 3D animation program Poser 6, © Curious Lab). A centrally
15 positioned human avatar faced either the left or right wall (Table 2). On 50% of trials the
16 avatar's position meant that s/he saw the same dots as the participants (Consistent condition).
17 On 50% of trials the avatar's position meant that s/he could not see some of the dots that were
18 visible to the participants (Inconsistent condition). Indices of Conflict (inconsistent –
19 consistent perspectives) and Focus (self-perspective – other perspective) were calculated as
20 per Bukowski and Samson (2017). Inverse Efficiency Scores (IES; response time / 1 – error
21 rate) were calculated for these conditions². A higher value in the Conflict index indicated
22 greater difficulty in handling conflicting perspectives, while positive values in the Focus
23 index indicated better performance in taking the other person's perspective than the self-
24 perspective (more altercentric rather than egocentric).
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41
42
43

44 45 *Director task* 46

47
48 In a 4 x 4 experimental grid, a critical instruction was given by the director that could refer to
49 a target object (mutually visible to the participant and instructor), or to a competitor object
50 (located in one of the covered slots, and so visible only to the participant). In order to choose
51
52
53
54

55
56
57 ² Use of IES is not recommended if speed-accuracy trade-offs are shown (indicated by no positive correlation
58 between response times and error rates) and if the average error rate is above .10 (see Bukowski & Samson,
59 2017). The correlation between response time and error rate was positive ($r(142) = .20, p < .01$), and the mean
60 error rate across conditions was 0.06 (standard deviation = 0.07), meaning both recommendations for using IES
were met.

1
2
3 the target object, the participant needed to consider the instructor's perspective. The
4
5 remaining objects in the grid were unrelated. In the equivalent control grids, the competitor
6
7 object was replaced by another unrelated object.
8
9

10
11 The measure taken was the number of errors made to ambiguous trials (where the item in the
12
13 instruction could refer to a competitor and a target object such as 'mouse' referring to either a
14
15 computer mouse or a small mammal, for instance) and relational trials (where the best fitting
16
17 object to the instruction was not mutually visible. For example, referring to a 'small ball',
18
19 where the smallest ball was a golf ball only visible to the participant, but the smallest
20
21 mutually visible ball was a tennis ball).
22
23
24

25 ***Task order***

26
27
28 The order of the tasks was fixed so that participants were exposed to identical stimulus
29
30 contexts (stimuli and order; see Carlson & Moses, 2001; Carlson et al., 2004; Friedman &
31
32 Miyake, 2004; Miyake et al., 2000; Miyake, Friedman, Rettinger, Shah & Hegarty, 2001).

33
34 This was done because a fixed task order is optimal for detecting correlations (e.g. Carlson &
35
36 Moses, 2001; Carlson et al., 2004; Friedman & Miyake, 2004; Miyake et al., 2000; Miyake,
37
38 Friedman, Rettinger, Shah & Hegarty, 2001). To check whether the performance on tasks
39
40 influenced one another, perhaps due to there being a finite resource for executive components
41
42 (Muraven & Baumeister, 2000), participants completed the Go / No-Go task at the start and
43
44 end of each session, and results compared. These showed no difference, suggesting that
45
46 fatigue and/or influence of similar tasks on performance did not occur.
47
48
49
50

51
52
53
54
55 The overall task order was as follows:
56
57
58
59
60

1
2
3 Go / No Go Task - L1 VPT (ToM) - Shape-Matching Task - Go / No Go Task (response
4 inhibition)³ - Stop-signal Task - Director Task (ToM) - Go / No Go (picture) Task. The tasks
5
6 were split into two sessions. The first session lasted for approximately 70 minutes and
7
8 consisted of the Go / No Go, Visual Perspective and Shape-Matching tasks, as well as the
9
10 repeat of the Go / No Go task⁴. The second session also lasted for approximately 90 minutes
11
12 and consisted of the Stop-Signal, Director and Go / No Go (picture)⁵. There were breaks
13
14 within each task and between each task, so that participants were not tested continuously for
15
16 the period of the sessions. Participants did the sessions on the same day (with a break
17
18 between them) or on separate days (maximum gap between sessions was three weeks).
19
20
21
22
23
24

25 *Analytical procedure*

26 *Data screening*

27
28 The data set was checked for univariate outliers, and pairwise plots examined for any
29
30 heteroscedasticity. Multivariate outliers were checked as per Tabachnick and Fidell (2001),
31
32 resulting in 12 participants being excluded. Variances for the dependent variables were
33
34 adjusted to all be within a 10:1 ratio (Kline, 2005). The final sample for analysis consisted of
35
36 142 participants (M age = 21.76, SD age = 4.37), with 28 males. This resulted in a total of
37
38 1132 data points.
39
40
41
42
43
44

45 After variance adjustment and transformations, the final descriptive statistics for the
46
47 dependent and independent variables were as shown in Table 1.
48
49
50

51 Table 1. Final task descriptives

52 Measure	53 M (SD)	54 Variance	55 Reliability ⁶
------------	-----------	-------------	-----------------------------

56 ³ This was a repeat of the first task in the session to compare performance at the start to the end of the session to
57 see the effect of a.) fatigue on performance, and b.) the possibility of the reduction in the resource of self-control
58 affecting performance by the end of the session (Muraven & Baumeister, 2001).

59 ⁴ And the Simon Task which was not included in the final analyses

⁵ And Cued Recall task which was also not included in the final analyses

60 ⁶ Split-half reliabilities

Shape-Matching (ms) (square root transformation)	21.56 (4.88)	23.77	.92
Go / No Go (FAR)	4.28 (2.12)	4.51	.93
Go / No Go (picture) (FAR; Bird/Mammal) ⁷	6.17 (3.05)	9.28	.74
Stop-Signal (SSRT) (log 10 transformation)	16.33 (6.74)	45.52	.99
Director Task (errors) (log 10 transformation)			
Ambiguous	2.34 (2.41)	5.79	.59
Relational	2.75 (2.66)	7.07	.83
Visual Perspective Indices (IES)			
Conflict	3.62 (2.25)	5.06	.85
Focus	-.07 (2.13)	4.55	.88

An initial correlation matrix between the variables is shown in Table 2. For the inhibitory control tasks, positive correlations were shown between the Shape-Matching and Stop-Signal tasks, the Go/No-Go and Go/No-Go (picture) tasks and the Go/No-Go and Stop-Signal tasks. While these are relatively low, this is common for tasks measuring inhibition (e.g. Friedman & Miyake, 2004) and may reflect task impurity. A positive correlation was shown between the Director task variables, and a negative one between the L1 VPT variables. The Shape-Matching task had positive correlations with both the Director (relational) variable, while the Go/No-Go (picture) task had positive correlations with both measures of the Director task. The Stop-Signal task also had a positive correlation with the L1 VPT (Conflict) variable.

Table 2. Correlation matrix between variables

	Shape Matching	Go NoGo	Go NoGo (picture)	Stop-Signal	Director Task (ambiguous)	Director Task (relational)	Visual Perspective (Conflict)
Go NoGo	-.04	-					
Go NoGo (picture)	.00	.23**	-				
Stop-Signal	.15	.18*	.08	-			
Director (ambiguous)	.09	.00	.34**	.02	-

Visual Perspective (Conflict)	.06	.14	.00	.24**	-.03	-.04	-
Visual Perspective (Focus)	-.02	.08	-.04	.02	.02	-.03	-.18*

* $p < .05$, ** $p < .01$

⁷ As FAR for the bird and mammal trials were significantly correlated and followed the same pattern, they were collapsed to form a single FAR for the go / no go (picture) task

Models

Analyses were carried out using AMOS 25. Path analysis aims to arrive at the most parsimonious model that explains the underlying data and does not significantly differ from it. Increasing the number of parameters in a model tends to improve fit, but necessarily decreases parsimony. The best model optimises fit and parsimony.

While the correlation matrix suggests that for the L1 VPT task, there was only a relationship between inhibitory control and the Conflict Index, in order to test the hypothesis that inhibitory control accounts for self/other perspective interference and egocentrism, paths from all inhibitory control tasks to all ToM measures were included in Model 1 (Figure 1, Appendix B). In the second model, all non-significant paths were removed (Figure 2, Appendix B). In model 3, covariances between the inhibitory control variables that were suggested by modification indices were added. This resulted in the final model (Figure 1) which outlines paths from differing inhibitory control variables to both Director task variables and the Conflict index of the L1 VPT task. This model also evidenced relationships between the inhibitory control variables. Due to the sample size and number of parameters, Bollen-Stine bootstrap analyses were conducted to more robustly assess model fit.

Results

Full descriptions, figures and tables for models 1 and 2 are shown in Appendix B and described in brief below.

Initial Model

No relationships were found between the Go / No-Go or Stop-Signal tasks and either of the Director task variables. The Go / No-Go (picture) task predicted performance on both

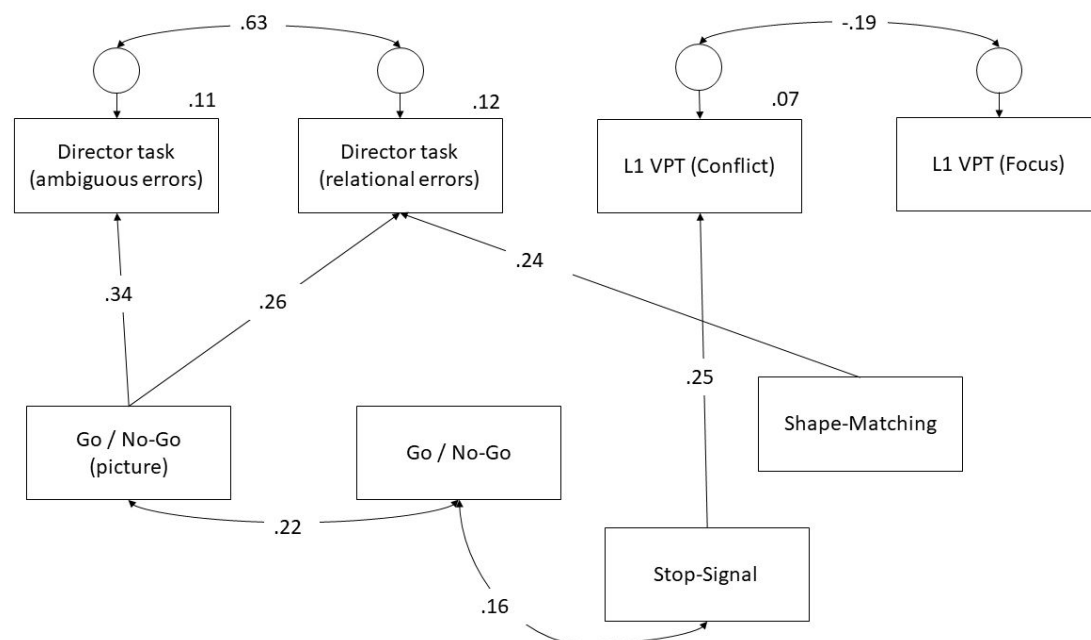

1
2
3 ambiguous and relational variables of the Director task, while the Shape-Matching task only
4
5 predicted performance on the relational variable. The Stop-Signal task predicted performance
6
7 on the L1 VPT Conflict Index, and no tasks predicted performance on the L1 VPT Focus
8
9 Index.
10
11

12 13 **Model 2**

14
15
16 Non-significant paths were removed, resulting in only the paths described in the initial
17
18 model. Model comparisons suggested that removing these paths did not significantly affect
19
20 the overall model fit ($X^2(12) = 6.29, p = .90$).
21
22

23 24 **Final model (model 3)**

25
26
27 For model 3, covariances between the Go / No-Go and Go / No-Go (picture) tasks and
28
29 between the Go / No-Go and the SST task were added (Figure). This significantly improved
30
31 the model fit ($X^2(2) = 11.38 p < .01$).

58 Figure 1. Model 3 (standardised coefficients)
59
60

The parameter estimates in Table 3 show that approximately 6% of the variance in the Conflict index was explained by the model, with around 11-12% of the variance of the director task (for both ambiguous and relational DVs) explained.

Table 3. Parameter estimates for final model (model 3)

Path	Unstandardised Estimate (Standard Error)	Standardised Estimate
Shape-matching → Director (relational)	.13 (.03)	.24***
Go/No-Go → Director (relational)		
Go/No-Go (picture) → Director (relational)	.22 (.07)	.26***

e4 (L1 VPT (Focus))	4.73 (.56)***	
Squared Multiple Correlations		
Director (relational)	.12	
Director (ambiguous)	.11	
L1 VPT (Conflict)	.06	
L1 VPT (Focus)	.00	

* $p < .05$, ** $p < .01$, *** $p < .001$

The model parameters for the final model (Model 3; Table 4) show that the fit was excellent.

Table 4. Model fit parameters

	CMIN	df	<i>p</i>	NFI	CFI	AIC	RMSEA	Low	High	Bollen-Stine Bootstrap <i>p</i>
Model 1	17.35	10	.07	.88	.94	69.35	.07	.00	.13	.14
Model 2	23.64	22	.37	.84	.99	51.64	.02	.00	.08	.36
Model 3	12.26	20	.91	.92	1.00	44.26	.00	.00	.03	.87

A power analysis was conducted on the final model fit values and sample size using Preacher and Coffman's (2006) power and sample size calculator for RMSEA. This suggests that the current sample size has a power of .92 to detect whether this was a poor fitting model⁸.

Testing whether the sample size was sufficient for the final model showed that an ideal sample size should be 107 (with .10 as the RMSEA value for a poor fit; Kenny, 2014⁹). Kline (2005) suggests a 10:1 ratio for free parameters as a realistic figure, which gives an estimated sample size of 80 for the final model. The current sample size is therefore appropriate for the current analyses.

Discussion

In the largest study to date, this research examines individual differences in adults' performance on two ToM tasks, with a particular focus on their ability to manage interference between self and other perspectives. Since this individual difference approach is relatively novel in relation to ToM in adult participants, it is noteworthy that two widely-used tasks – the Director Task (Keysar, Lin & Barr, 2003) and the Level-1 Visual Perspective-Taking Task (Samson et al., 2010) each showed reliable measurement characteristics. Moreover, performance on the two minor trial variants within the Director Task was strongly correlated.

⁸ Observed power = .8, df = 20, n = 142, null RMSEA = .01 (excellent fit), alternative RMSEA = .00 (final model value).

⁹ Observed power = .8, df = 20, null RMSEA = .01, alternative RMSEA = .10

1
2
3 For the L1 VPT task, the relationship between Focus and Conflict indices was negative,
4 suggesting that those better at handling conflicting perspectives were more likely to be better
5 at taking the ‘other’ perspective¹⁰.
6
7
8
9

10
11 Against this background of successful measurement there was a striking lack of any
12 relationship between indices of these effects in the Director Task and L1-VPT. There was no
13 evidence that the need to control interference between self and other perspectives drew upon
14 a common process in these two tasks (no support for Prediction 1), whether that is a common
15 process specific to self/other control (Bardi, Six & Brass, 2017) or a common process that
16 relies on domain general executive control (Bull et al., 2008; German & Hehman, 2006;
17 McKinnon & Moskovitch, 2007). Self/other interference in the two ToM tasks was correlated
18 with measures of domain-general executive control (support for Prediction 2). However, each
19 ToM task correlated with different executive control tasks. Since no relationship was
20 observed between measures of self/other control, we could not examine whether such a
21 relationship would be mediated by domain-general executive control (Prediction 3).

25
26
27
28
29
30
31
32
33
34
35
36

37 These results are surprising in light of the convergent evidence presented in the
38 introduction suggesting that self/other interference and egocentrism are very commonly
39 reported phenomena across multiple ToM tasks and other social tasks. Debate has mainly
40 concerned whether the process for handling such interference is specific to self/other control,
41 or domain-general (e.g., Cook, 2014; Happe et al., 2017; Hartwright et al., 2016). The
42 underlying assumption that we are studying one phenomenon is usually taken for granted. Of
43 course we must be cautious about rejecting this assumption, particularly on the basis of the
44 absence of predicted effects. In what follows, we first consider whether our tasks were
45 suitable for use as *measures* of individual differences in self/other interference. We next

18 *Limitations in ToM measures?*

19
20
21 Both the Level-1 Visual Perspective-taking Task and the Director Task generated the
22
23 anticipated self/other interference effects and measured individual differences in performance
24
25 reliably. However, this does not entail that they reliably measured individual variability in
26
27 self/other interference (we also note that while task reliabilities were generally high ($< .7$) the
28
29 reliability for ambiguous errors in the Director task was .59). It is important to acknowledge
30
31 that both tasks were devised as laboratory platforms to investigate egocentrism and self/other
32
33 interference, primarily through manipulation of task conditions that might affect
34
35 performance. As recently discussed in the context of individual differences in executive
36
37 control (Friedman & Miyake, 2017; Hedge et al., 2018), such laboratory tasks are typically
38
39 developed to minimise individual differences between the performance of participants, in
40
41 order to maximise the chances of observing between-condition effects.
42
43
44
45
46
47

48 In response to such limitations, a small number of other tasks have been specifically designed
49
50 to quantify individual differences in ToM (see Apperly, 2012). However, these tasks generate
51
52 variance by requiring more subtle or complicated judgements, and in doing so become more
53
54 opaque with respect to the underlying processes contributing to variance (e.g., Apperly,
55
56 2010). A significant objective for future work is therefore to devise new tasks that maximise
57
58 individual differences, not just in overall “scores”, but in theoretically motivated processes
59
60

1
2
3 related to ToM, such as self-other interference (or perhaps other parameters related to minds,
4 rather than representing mental states, Conway, Catmur and Bird, 2019). With this important
5 caveat in mind, we nevertheless note that both the L1 VPT and the Director Task have
6 previously shown evidence of construct validity, through correlations with well-established
7 measures of individual differences relevant to social functioning (Focus scores for L1 VPT
8 correlate with the Interpersonal Reactivity Index, Bukowski & Samson, 2017; Errors on the
9 Director Task correlate with traits related to both autism and schizophrenia, Abu-Akel et al.,
10 2015). We consequently believe the present findings are interpretable, given appropriate
11 caution.
12

14
15
16
17
18
19
20
21
22
23
24

25 A further question is whether these tasks actually measure ToM at all, since recent
26 evidence suggests that the processing they entail may not be domain-specific to ToM (e.g.,
27 Santiesteban, 2014, 2015, 2017). There has been longstanding discussion about the extent to
28 which ToM relies upon distinctive cognitive processes. One position is that reasoning about
29 mental states makes unique cognitive demands (e.g., Leslie., 1987) that are met by a domain-
30 specific module (e.g., Baron-Cohen, 1995; Leslie et al., 2004). A different, and widely-held
31 position is that ToM is more domain-general, making similar cognitive demands to a much
32 broader category of reasoning problems, including reasoning about signs, words and pictures,
33 as well as counterfactual thinking (Perner & Leahy, 2016; Riggs et al., 1998; Roessler &
34 Perner, 2013). Both positions are compatible with a significant role for executive processes in
35 the performance of ToM tasks, but the domain-general account also allows that executive
36 processes contribute directly to representing or reasoning about mental states. Researchers
37 have long sought evidence of domain-specificity by comparing behavioural performance
38 when participants reason about mental states versus pictures, signs, or other non-mental
39 perspectives, with relatively few results supporting domain-specificity. For example, while
40 children with autism perform worse on false belief tasks than comparable false photograph
41

60

1
2
3 tasks (Leslie & Thiass, 1992) they perform at similar levels on false belief and false sign
4
5 tasks (Iao et al., 2014). Typically-developing children's performance on false belief tasks is
6
7 closely correlated with performance on false sign tasks (Leekam et al., 2008) as well as
8
9 synonym judgement tasks (Doherty & Perner, 1998), all of which require reasoning about
10
11 metarepresentations but not mental states (Perner & Leahy, 2016). In response to such results
12
13 it has been argued that false belief tasks (and ToM more generally) make demands that are
14
15 exacting, and meaningful in terms of understanding patterns of performance in children and
16
17 adults, but these demands are not domain-specific to ToM (e.g., Apperly 2010). To our
18
19 knowledge, nobody has used such results to argue that false belief tasks do not entail
20
21 representing mental states. One reason for this might be that participants in these tasks are
22
23 often directly requested to reason about mental states.
24
25
26
27

28
29 Specifically in relation to the LIVPT and Director tasks used in the current study,
30
31 recent work that has tested the domain-specificity of these effects and found evidence that
32
33 similar effects are obtained when the avatar is replaced with an arrow and when the director
34
35 is replaced with a camera the view of which conditionalises their responses in the same way
36
37 as the director (e.g., Santiesteban, 2014, 2015, 2017). These results fail to find support for the
38
39 domain-specificity of the effects in the LIVPT and Director tasks, but as illustrated above,
40
41 there is no necessary link between ToM and domain-specificity in accounts of ToM, and
42
43 plenty of reasons for thinking that domain-general executive functions play central roles in
44
45 enabling ToM. Moreover, while it cannot be ruled out that participants ignored instructions to
46
47 think about the perspectives of the avatar and the director, we see no evidence for this (e.g.,
48
49 Apperly et al., 2010), and no reason why participants would have behaved in this way.
50
51
52
53

54
55 The concern that participants may not have been representing mental states at all has
56
57 most force in the "self" condition of the LIVPT task in which participants were not explicitly
58
59 asked to judge the avatar's perspective. Instead putatively "implicit perspective-taking" is
60

1
2
3 inferred from interference effects on participants' judgements of their own perspective. In
4 this case it is informative to view results from the Self and Other trials separately (see
5 Appendix C). These analyses find that the "altercentric interference" effect for Self trials is
6 not related to any of the executive tasks in the present study, but it is related to "egocentric
7 interference" on Other trials of the LIVPT task. Of course this evidence does not demonstrate
8 that perspective-taking *is* occurring, and different patterns may have been obtained with
9 different inhibition tasks. Nor would a significant correlation have demonstrated that
10 perspective-taking was *not* occurring; it would not be surprising if the magnitude of
11 interference from the avatar's perspective varied as a function of an individual's inhibitory
12 capacity. However, as it stands, the present study provides no evidence that altercentric
13 interference reflects domain general inhibition and not perspective-taking, which is the
14 alternative hypothesis that has sometimes been proposed for this task (e.g. Heyes, 2014).

27
28
29
30
31
32

33 *Is self/other control a limiting step for healthy adults?*

34 Existing evidence suggests that self/other interference effects are particularly large in
35 children (who have limited executive control; Steinbeis, 2016), in individuals with brain
36 injury that has affected their capacity for executive control (e.g., Samson et al., 2005, 2016),
37 and in healthy adults under cognitive load (e.g., Qureshi et al., 2010). Healthy adults without
38 cognitive load also show self/other interference effects, and associated neural correlates
39 (Cook, 2015; Steinbeis, 2016). However, the fact that healthy adults must resolve self/other
40 interference in a given task does not mean that doing so is a limiting factor on their
41 performance such that individuals might vary in their capacity to resolve this interference
42 successfully. On this interpretation, there may be a common underlying process involved in
43 self/other control across different tasks, but since all healthy adults could meet this need
44 reliably it would not contribute to individual differences in performance that would correlate
45

1
2
3 between tasks. Correlations might only emerge if the ToM tasks placed sufficiently large
4 demands on self/other control that healthy adults did vary in their capacity to meet these
5 demands. Alternatively, the correlations that we did observe between self/other interference
6 effects and measures of domain-general executive function could suggest that our tasks were
7 indeed sufficiently taxing to generate at least some individual differences. However, these
8 correlations accounted for only a small proportion of the variance in performance, and the
9 fact that different executive tasks correlated with each ToM task calls into further question
10 the proposition of a common self/other factor between the ToM tasks.
11
12
13
14
15
16
17
18
19
20
21
22

23
24 *Self/other control and egocentrism may be a “family” of phenomena that place different*
25 *executive demands.*
26
27

28 It is a parsimonious hypothesis that all self/other interference effects arise from a
29 common underlying process, but this may not be the best explanation for these phenomena.
30 The need to distinguish mental states related to self and other surely is a core feature of ToM
31 tasks, but it has been suggested that this feature can give rise to interference effects in
32 different ways, and at different stages of processing (e.g., Apperly, 2010). This account
33 would predict a “family” of self/other interference phenomena that resemble each other at a
34 general level of description, but are not necessarily correlated because different demands are
35 made at different stages of processing. For example, in the L1 VPT task participants must
36 both *calculate* the perspectives of self and other and *select* the correct response based on one
37 or other of these perspectives (Qureshi et al., 2010). Evidence from event related potentials
38 suggests that perspective calculation occurs first, and involves posterior cortex (putatively
39 temporoparietal junction), while selection occurs later and involves the frontal cortex
40 (putatively the right inferior frontal gyrus; McCleery et al., 2011). Importantly, *both*
41 calculation and selection ERP effects are influenced by self/other consistency, but
42

52
53
54
55
56
57
58
59
60

1
2
3 participants' response times and errors on this task appear to reflect the effect of self/other
4 consistency on selection of a response according to the perspective required for that trial. The
5 correlation observed in the present study between the conflict index from the L1 VPT task
6 and the Stop Signal Task suggests that this selection may occur very late in processing,
7 perhaps after responses according to both self and other perspectives have already been
8 initiated.
9

10
11
12 In contrast, while the Director task requires level-1 visual perspective-taking, it
13 additionally requires that information about the director's perspective is integrated with his
14 instructions about which objects to move. Studies of eye movements suggest that participants
15 may process the director's perspective in anticipation of his instruction, and that egocentric
16 eye movements and errors originate in difficulty with the subsequent process of integrating
17 this information with his instruction (Barr, 2008). The proposal that egocentric effects in the
18 director task have a different functional origin from self/other interference effects in the L1
19 VPT task may explain why these effects did not, themselves, correlate, and why different
20 domain-general executive tasks were correlated with each effect¹¹.

43 ***Conclusion***

44
45 From the largest exploration of individual differences in in ToM and inhibitory control to
46 date, we found that self/other interference effects in L1 VPT and Director Task were
47 dissociable. Individual differences in performance on the two tasks were unrelated, and
48 differences in performance on each task were related to different tests of executive function.
49

50 Both findings converge with recent evidence from individual differences in perspective-
51 taking during psycholinguistic tasks (Ryskin et al., 2015). We suggest that self/other
52

54
55
56
57
58
59 ¹¹ A more specific discussion of the relationship between the individual executive tasks, and their relationships
60 with the ToM tasks is in section A4 of Appendix A.

1
2
3 differences are part of the essence of ToM tasks, but that they give rise to interference effects
4
5 in a variety of ways, at different stages of processing, resulting in a variety of requirements
6
7 for executive control processes. We also suggest that the requirement to resolve self/other
8
9 interference may not be the only, or even the most significant, limiting step for healthy
10
11 adults' performance on typical tasks. Future work is needed to understand whether self/other
12
13 interference sometimes places a higher burden for adults, and also to understand other factors
14
15 that may limit adults' ToM performance and so may explain individual differences in social
16
17 ability.

Appendix A1

IC task selection and predictions

The classification and choice of inhibitory control tasks was based on Friedman and Miyake (2004). Their initial classifications were designed to measure the different stages of the informational processing of inhibition. This starts with resistance to distracter interference (selecting relevant information and ignoring irrelevant information), followed by resistance to proactive interference (once information has entered working memory) and, finally, prepotent response inhibition (select relevant responses and resist incorrect ones). They found that resistance to distracter interference and prepotent response inhibition loaded on the same latent variable (defined as Response-Distracter Inhibition). As such, it was concluded that Response-Distracter Inhibition and Resistance to Proactive Interference are distinct components of inhibition (Friedman & Miyake, 2004). Our tasks we used were therefore originally chosen with the objective of identifying latent variables for these two components and then assessing their relationship to ToM.

In Friedman & Miyake (2004) Response-Distracter Inhibition tasks included the Go / No-Go task (though these also include some requirement for response selection), Stop-signal task and anti-saccade tasks. Due to laboratory infrastructure, the anti-saccade task could not be used, so we selected a variant Go/No-Go task where the Go and No-Go judgements were based on semantic and orthographic information, as opposed to perceptual information. This follows the principle that latent-variables are best estimated using tasks that differ in as many respects as possible other than the hypothesised underlying common process. From the tasks that Friedman and Miyake (2004) found to load on on the latent variable for Resistance to Proactive Interference we selected the Cued Recall task, Simon task and Shape-Matching tasks.

1
2
3 However, initial data screening and confirmatory factor analyses showed that two of the
4 chosen tasks (Simon and Cued Recall tasks) showed no relationship between any of the other
5 tasks and low reliability respectively. We therefore had to exclude these tasks from further
6 analyses, and follow an alternative analytical approach of using the remaining tasks as
7 individual predictors.
8
9

10
11
12 Specific predictions about potential relationships between the individual inhibitory predictors
13 and the ToM tasks are as follows:
14
15

- 16
17
18
19
20
21 1.) The Director task involves the participant avoiding interference from their own
22 perspective when integrating information about the director's perspective with his
23 instructions, and also the need to avoid selecting a distracting incorrect response
24 (Barr, 2008). This leads to the expectation of a role for both Response-Distracter
25 Inhibition and Resistance to Proactive Interference, and therefore potential
26 relationships with any of the selected inhibition tasks.
27
28
29
30
31
32
33
34
35
36
- 37 2.) The L1-VPT Conflict index relates to interference between self/other perspectives,
38 and literature suggests that participant errors and response times reflect the effect of
39 self/other consistency on selection of a response (Apperly, 2010, Qureshi et al., 2010,
40 McCleery et al., 2011). This suggests a functional role for Response-Distracter
41 Inhibition, and so we predicted a relationship between L1-VPT Conflict index and
42 inhibition tasks involving Response-Distracter Inhibition. The Focus index represents
43 relative performance on judgments that relate to the self (versus other). As such, we
44 did not expect to see a relationship with the Focus Index and inhibitory control tasks.

Appendix A2

Task methodology (further details)

Shape-matching task

The shapes used were taken from DeSchepper and Treisman (1996); eight each of green (target), red (distracter) and white (matching) shapes. The task was simplified to measure resistance to distracters and resistance to inappropriate responses, rather than negative priming as in DeSchepper and Treisman (1996). This was done by presenting the distracter shapes at the same time as target shapes in the experimental trials, which requires participants to actively keep the distracters from interfering with processing of the target shapes (Endo, Saiki & Sato, 2001).

The shapes measured 135 x 124 pixels and were presented on the left (green/red shapes) and right (white shape) of a 300 x 300 pixel black square. The number of times each type of shape occurred was balanced across the task. Across the total of 112 trials (56 distracter trials and 56 no-distracter trials), the number of times each shape occurred was balanced in four separate blocks of 28 trials. Within these, the number of matching (green = white) and non-matching (red = white) stimuli were also balanced.

Participants were instructed to decide whether the green (target) shape matched the white shape. They were told to ignore the red (distracter) shape when it was present. Each trial had the following procedure: The participants were presented with a READY prompt, to which they had to respond to in order to proceed. A blank screen was then shown for 1100ms, followed by a fixation point for another 500ms. The shapes were then presented until the participant responded. Then another blank screen was shown for 100ms, upon which the

READY prompt appeared for the start of the next trial. Images of the trials are shown in

Figure 1:

Figure 1. Trial images: Top left = no distracter, match; Top right = distracter, match; Bottom left = no distracter, no match; Bottom right = distracter, no match.

Cued Recall task

The task was designed to measure pro-active interference and was based on the study of Tolan and Tehan (1999). Participants were presented with either one block (filler trials) or two blocks (control and experimental trials) of four serially presented words (one per 1000ms). In all trials this was followed by a numerical magnitude judgment task as a distraction¹. Participants were then presented with a cue word to vocally recall a word from the only block for filler trials or from the second block (control and experimental trials). The

¹ Participants were presented with eight serially presented random numbers of two digits (one per 1000ms), and had to judge aloud if they were above or below 50.

1
2
3 cue word was a category word related to the target word in the second block, but also to a foil
4 word in the first block of experimental trials (there was no foil word in control trials). The
5 foil words were always a more common instance of the category given by the cue word (than
6 the target words), so increasing pro-active interference. An example experimental trial is
7 shown in Figure 2.

String instrument

Figure 2. Cued Recall experimental trial (for the purposes of illustration, the blue border indicates foil word, and the red border indicates target word; these borders were not present in experimental stimuli)

41 The experiment consisted of 10 one block filler trials and 40 two block trials, the latter
42 consisting of 20 control and 20 experimental trials. To increase interference, the ALOUD
43 block always came before the SILENT block. This was followed by the distracter task and
44 then the cue word. The dependent measure was the number of correct control trials minus the
45 number of correct interference trials. This was chosen because the number of correct control
46 trials was taken to be the measure of the participants' general recall ability (dealing with the
47 interference caused by the mixed modality (reading aloud v silently), and the distracter task).
48 The interference trials additionally had pro-active interference from the foil word in the first

1
2
3 block. The measure therefore assessed participants' ability to deal with pro-active
4 interference while taking into account their general recall ability.
5
6
7

8 *Simon task*

9
10 The task was based on Peterson et al. (2002). Participants were shown horizontally-orientated
11 arrows (left or right), presented on the left or right of a central fixation point. Participants
12 were instructed to respond according to the orientation of the arrows, not the position. As the
13 arrow position is visually more salient than the arrow orientation, responding to the
14 orientation requires the inhibition of any response to the position. The majority of trials were
15 congruent for orientation and position (328 congruent, 82 incongruent)., with left and right
16 positions and orientation balanced equally across four blocks of 102 trials for a total of 408
17 trials.
18
19
20
21
22
23
24
25
26
27
28
29

30 Each trial began with a fixation point for 200ms, followed by an arrow for a maximum of
31 1300ms or until a response was made. The difference between response times to accurate
32 incongruent and congruent trials was taken to be a measure of any inhibitory processing cost
33 present only in the incongruent trials (any processing cost common to the incongruent and
34 congruent trials would be accounted for).
35
36
37
38
39
40
41
42
43

44 *Go / No-Go task*

45
46 The experiment consisted a total of 520 trials across eight blocks of 65 experimental trials
47 (each block also had an additional five trials at the start (these were eliminated in analyses as
48 practice trials). There were either eight or ten no go (K) trials (and a corresponding 57 or 55
49 go trials) in each block Each letter was presented centrally on a black screen.
50
51
52
53
54
55

56 Participants viewed a series of letters presented on a computer screen to which they had to
57 respond by pressing the spacebar, except for the letter 'K'. If the participant responded
58
59
60

1
2
3 incorrectly to the letter K, a tone would be heard for 250ms. Each trial consisted of an initial
4
5 fixation cross for 250ms, followed by a letter. Each letter remained on-screen for 500ms, or
6
7 until the participant responded.
8
9

10 11 12 13 14 15 16 17 *Go / No-Go (picture task)*

18
19 This task was based on the study of Schmitt et al. (2000). Participants were presented with
20
21 images of either birds or mammals (there was a familiarisation procedure prior to the task²).
22
23 Participants responded by pressing the Q key if a bird was shown, and with a P if the image
24
25 was of a mammal. If the name of either began with a vowel, they were instructed not to
26
27 respond. This task creates a Go/No-Go situation because an initial Go decision is based on
28
29 the rapidly-available semantic information (bird/mammal category) which must then be
30
31 cancelled or allowed based on later-available phonological or orthographic information, (van
32
33 Turrenout et al., 1997). The majority of images were go trials (36 each for birds and
34
35 mammals, compared to 9 no-go trials for each), repeated twice and balanced across eight
36
37 blocks for a total of 180 trials. The first three trials were removed from further analyses as
38
39 practice trials.
40
41
42
43
44

45 During the experiment, after an initial fixation cross for 250ms, the images were presented
46
47 for 750ms, or until the participant responded. If the participant responded incorrectly, a tone
48
49 was heard for 250ms. The images were scaled to 500 x 500 pixels.
50
51
52
53
54
55

56
57 ² The participants were shown (serially) all the images of birds and mammals, together with their names, at the
58 start of the experiment (each image remained on-screen until the participant pressed a key). They were then
59 shown the images again, in a different order, for 3000ms, in which time they were instructed to name each
60 image. Pilot work had already shown people were familiar with the mammals and birds used.

Stop-signal task

A total of 256 trials across eight blocks were presented to participants, consisting of either a “X” or “O”. After an initial fixation cross for 500ms, the stimuli were shown on-screen for 1000ms or until the participant responded, followed by a blank screen for 2000ms (or again until the participant responded). 64 of the trials were stop trials, where a tone was heard after a variable delay, with the remaining being go trials, all balanced across blocks. Participants were instructed not to respond if they heard the tone, and the stop signal delay started at 250ms after stimuli presentation and then followed a dynamic tracking procedure (+50ms if they responded correctly, and -50ms if incorrectly). Letters were presented centrally on a 400 x 300 pixel black screen.

L1-VPT task

There were a total of 96 matching trials: 48 trials in which participants were asked to verify their own perspective (with 24 consistent perspective trials and 24 inconsistent perspective trials) and 48 trials in which participants were asked verify the avatar’s perspective (with 24 consistent perspective trials and 24 inconsistent perspective trials). In addition to these 96 test trials, 96 mismatching filler trials were included (with the same distribution as for test trials) as well as 16 additional anti-strategy filler trials (eight matching and eight mismatching in which no circles were pinned on the wall). The 208 items were split into four blocks of 52 items. Each trial image measured 640 x 480 pixels, with the avatar presented centrally.

Between zero and three dots were presented at the avatar’s eye level on neither, both or either wall.

Before being shown the image, participants were cued with a verbal perspective description that informed them which perspective to take (“you” versus “he”/”she”) and which perspective content to verify (i.e., a number of dots visible, between zero and three). They

1
2
3 were then asked to decide whether the cue information matched the relevant content shown in
4 the image. In half of the trials, the cue matched the image and on the other half the cue did
5 not match the image. An initial fixation cross was on-screen for 750ms, followed by the cues,
6 which were also shown for 750ms. The gap in between fixation and cues was 500ms. The
7 stimuli picture remained on-screen until the participant responded. If no response was
8 received within 2000ms of the picture being on-screen, the trial was recorded as no response.

Figure 23. L1 VPT trial conditions

Director task

1
2
3 Stimuli replicated those in Apperly et al. (2010). A total of 32 different grid arrays were used,
4 each with 16 slots (4 x 4 grid). In each grid, 5 slots were occluded from the view of the
5 director (male figure with a male voice), with the remaining 11 visible to the participant and
6 the director. These were arranged in one of four different patterns, sized at 720 x 540 pixels.
7
8 Each grid contained eight items, created from simple cartoon images. There were 128
9
10 instructions used across the experiment, with between three and five for each grid. Two
11
12 practice grids were also used with the same layout.
13
14

15
16 Sixteen of the grids were ‘experimental’ grids, with one critical instruction that could refer to
17
18 an object in an occluded slot (if only the participant’s perspective was taken into account), or
19
20 to one in a mutually visible slot (if the director’s perspective was accounted for). The position
21
22 of this critical instruction varied between first and fourth in the series for each grid. Half of
23
24 the experimental grids were ‘relational’ trials, and half were ‘ambiguous’ trials. Relational
25
26 instructions followed the pattern “Move the [adjective noun] one slot left/right/up/down”, and
27
28 the noun occurred on average 1,047ms after the start of the instructions. For ambiguous trials,
29
30 the instructions followed the formula “Move the [noun] one slot left/right/up/down”, and the
31
32 noun occurred on average 742ms after the instruction. All other instructions were filler items
33
34 that followed the same pattern of the critical instruction, and always referred to mutually
35
36 visible objects.
37
38

39
40 The remaining 16 grids were matched control grids (also half relational and ambiguous),
41
42 where the item referred to in the critical trial was replaced with an item that could not be a
43
44 potential referent (e.g. aeroplane for small ball). Every grid was presented for 5000ms before
45
46 instructions began, and these were then given at 5000ms intervals. An example grid is shown
47
48
49
50
51
52
53
54 in Figure 34.
55
56
57
58
59
60

Figure 4. Example grid for a relational grid of the Keysar task

Critical instruction: Move the small ball down one slot

In the experimental grid, the smallest ball from the participant's viewpoint is the competitor item (golf ball), but the target item (the smallest ball from the director's viewpoint) is the tennis ball.

In the control grid, the smallest ball from the participant viewpoint is the target item (tennis ball), which is the same as for the director.

Appendix A3

Individual task results

The data screening process consisted of several steps. The following steps were adapted from those used by Friedman and Miyake (2004) and Oberauer (2005) in order to reduce the effect of any extreme response time values on the mean.

The critical dependent variables of the various tasks were calculated, and any values more than three standard deviations above or below the task mean were replaced by the cut-off value (of three standard deviations above or below the mean)³. All pairwise plots were then examined for nonlinearity and heteroscedasticity. The distributions of the critical dependent variables were then checked, as were univariate outliers, and any transformations were carried out. Checks for multivariate outliers were then done, and finally the variance of each variable was examined and modified as per Kline (2005). Each task required different calculations for its critical dependent variable, which are all detailed below. The reliability of all the critical measures was calculated by adjusting split-half correlations using the Spearman-Brown prophecy formula (Salthouse et al., 2006). Each task was first analysed individually to establish that the expected effects were observed.

Go/No-Go

The data were analysed using a 2-way (position; start v end) repeated measures ANOVA. The dependent variable was the False Alarm Rate (FAR) on No-Go trials.

³ For the L1 VPT we followed the procedure of Samson et al. (2010) and used 2.5 SD rather than 3SD).

There was no difference in the performance of participants in the task carried out at the start of the session and the performance in the task carried out at the end of the session (see Figure A1; $F_{(1, 141)} = .35, p = .55, \eta_p^2 = 0.02$), so FAR was collapsed over position. FAR was significantly different from zero ($t(141) = 23.53, p < .01$).

Figure A1. FAR by session (bars = standard deviation)

As the distribution was skewed, a square-root transformation was carried out. The reliability of the measure was excellent (.93).

Go / No-Go (picture)

A repeated measures ANOVA was conducted, with image type (bird v mammal) as the condition, and FAR as the dependent variable. There was a main effect of image, with higher FAR for bird images than for mammals ($F_{(1, 141)} = 9.67, p < .01, \eta_p^2 = .07$; see Figure A2). However, due to the correlation between the FARs for birds and mammals suggesting similar processes were involved, they were collapsed to form a single FAR measure. The reliability of the measure was satisfactory (.74).

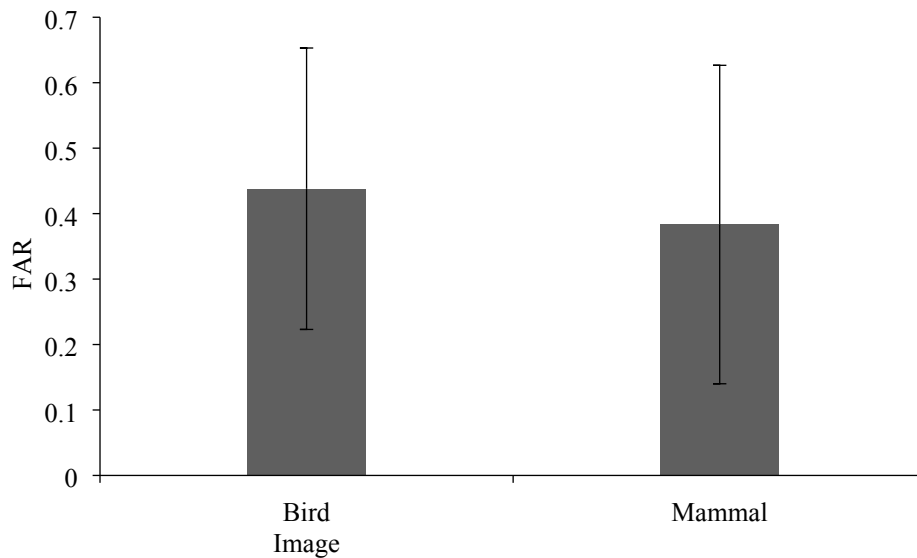

Figure A2. FAR by image (bars = standard deviations)

Stop-signal task

The critical dependent variable was the mean response time to the go trials (correct response only) minus the mean response time to the stop trials. The mean stop signal response time (SSRT) values of the participants was similar to that found in previous literature (232ms (SD = 237.09) compared with 189ms in Aron et al. (2003)).

The distribution of SSRT was extremely non-normal. In order to normalise the distribution the times above three standard deviations were replaced by the highest value below three standard deviations plus one (for the lowest above three standard deviations, plus two for the second lowest, etc.). This was done as described above in three waves – twice for values above three standard deviations, and once for values below three standard deviations, with two participant values being replaced (the mean SSRT after this trimming was 219ms (SD =

1
2
3 172.41)). These procedures are as described in Tabachnick and Fidell (2001). This resulted in
4
5 the distribution being reasonably normal. The reliability was excellent (.99).
6
7
8
9

10 11 12 *Shape-Matching Task* 13

14
15
16 Data were trimmed by condition for each participant individually, looking at correct
17
18 responses only (5.1% of the responses were incorrect). Response time values that were more
19
20 than three standard deviations away from the condition mean for a participant were replaced
21
22 by the cut-off value (of three standard deviations from the condition mean). This was done
23
24 for 1.41% of trials. A 2 x 2 repeated-measures ANOVA was used to examine the data. The
25
26 factors were distracter (present v not present) and match (did the target match the green
27
28 shape, yes v no) and the measure was the mean response time for each condition.
29
30
31
32
33
34
35

36 There was an effect of distracter ($F_{(1, 141)} = 122.73, p < .01, \eta_p^2 = .47$). If the distracter shape
37
38 was present, the response time was significantly longer than when the distracter shape was
39
40 not present (distracter = 1296.10ms > no distracter = 973.07ms). There was also an effect of
41
42 match ($F_{(1, 141)} = 25.13, p < .01, \eta_p^2 = .15$). Participants took significantly longer to respond
43
44 to trials in which the green shape did not match the white shape than to trials where they did
45
46 not (match = 1093.12ms < no match = 1176.05ms). There was an interaction between
47
48 distraction and matching ($F_{(1, 141)} = 4.65, p < .05, \eta_p^2 = .03$), as can be noted in Figure A3.
49
50 Errors were similar for all conditions (proportion of errors in distracter no match condition =
51
52 .07, in distracter match condition = .05, in no distracter no match condition = .04, in no
53
54 distracter match condition = .04), indicating that there was no particular trade-off between
55
56 speed and accuracy.
57
58
59
60

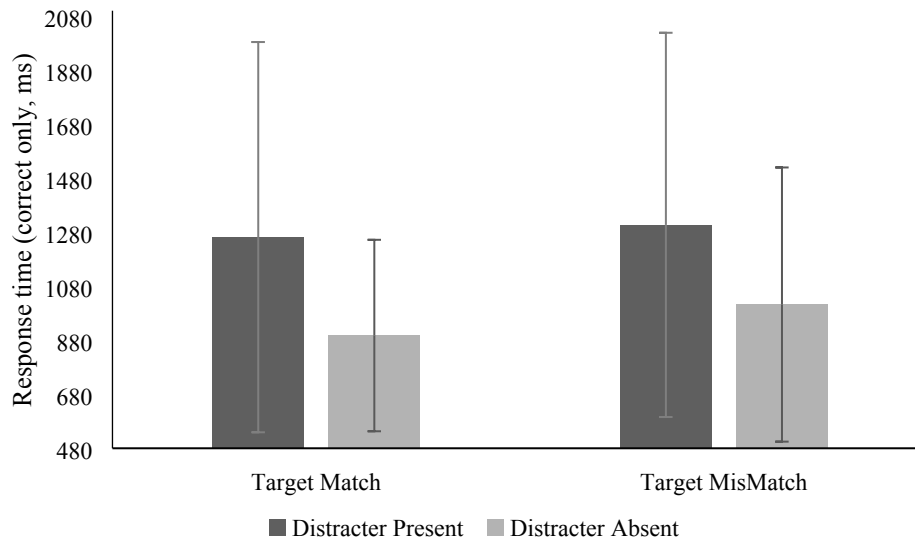

Figure A3. Response time by condition (bars = standard deviations)

Simple main effects showed that for both match and mismatch conditions, participants took significantly longer to respond to trials where the distracter was present (p 's < .01). When the distracter was present, there was no difference between the match and mismatch conditions ($p = .08$), but participants took longer to respond to the mismatch condition when the distracter was not present ($p < .01$).

The critical dependent variable was the difference in mean response time between the distracter no-match condition and the no distracter match condition. The distracter no-match condition appeared to have the largest amount of interference from the distracter shape, as this shape matched the target. The no distracter match condition had the least amount of interference, and gives a baseline measure of the response time to the simple matching process. The difference between these conditions is therefore a measure of the interference caused by the distracter shape only, which should require inhibitory control. Any values more than three standard deviations away from the mean were replaced by the cut-off value (of three standard deviations above or below the mean). The distribution of the critical shape

1
2
3 matching task dependent variable was extremely non-normal, so underwent a log 10
4
5 transformation resulting in a normal distribution. Reliability was adequate (.66).
6
7
8
9

10 11 12 *Cued Recall* 13 14

15
16 As the data analysed for the cued recall task were the number of correct trials, they were not
17
18 trimmed (9.5% of the responses were incorrect). Control and interference trial performance
19
20 was analysed, using a 2-way repeated measures ANOVA. In both trial types participants were
21
22 cued to recall a target word from a list (the second of two). In interference trial a foil word
23
24 was also present (in the first list of the two). The first list of words was always read aloud,
25
26 and the second set was always read silently. Before the analysis was carried out, missing
27
28 values for two participants⁴ on task were estimated through imputation and regression
29
30 estimation procedures. The result of the estimations from these two procedures did not differ
31
32 significantly, so the estimates from the imputation method using the program NORM
33
34 (Schafer, 1999) were used.
35
36
37
38
39

40 Participants were more accurate in the control condition than in the interference condition (F
41
42 $(1, 141) = 191.38, p < .01, \eta_p^2 = .59$; see Figure A4). This effect is probably due to the effect of
43
44 the foil word in the interference trials affecting recall of the target word, as expected. The
45
46 critical dependent variable was calculated as the difference between the number of correct
47
48 control trials and the number of correct interference trials. The mixed modality of the
49
50 presentation and distracter task were common to both trials, so this dependent variable should
51
52 remove any contribution from that. The dependent variable should therefore only measure the
53
54 level of interference caused by the foil word in recalling the target word, interference which
55
56
57
58
59

60 ⁴ These participants failed to complete the cued recall task due to time constraints (arrived late to session).

should be mediated by inhibitory control. The distribution of the critical dependent measure was normal, so no transformations were required. However, the reliability of the measure was extremely low (.12), so this measure was excluded from the final analyses.

Figure A4. Errors (N; bars = standard deviation)

Simon task

The data were trimmed by condition for each participant for correct responses only (5.3% were incorrect responses). Response time values that were more than three standard deviations away from the condition mean for a participant were replaced by the cut-off value (of three standard deviations from the condition mean). A 2 (position; left x right) x 2 (orientation; left x right) repeated-measures ANOVA was used to examine the data, with the dependent variable mean response time for correct trials.

There was no effect of the position of the arrow on the response time of participants ($F_{(1, 152)} = .77, p = .38, \eta_p^2 = .01$), whilst there was a significant effect of orientation ($F_{(1, 152)} = 36.34, p \leq .01, \eta_p^2 = .19$), with responses to left-orientated arrows significantly slower than to right-

orientated arrows. This may be due to the majority of the sample being right-handed participants.

There was a significant interaction between position and orientation ($F_{(1, 152)} = 567.16, p \leq .01, \eta_p^2 = .79$), as shown in Figure . Simple main effects were conducted to analyse this further.

Figure A5: Mean response times (and standard error) to differing positions and orientations of arrow

Simple main effects indicated that when the orientation and position of the arrow was congruent, response times were significantly faster, relative to when they were incongruent (all p 's $< .01$). The pattern of errors showed a similar effect, with more errors made when position and orientation were incongruent (.13) compared to when they were congruent (.35), indicating no speed – accuracy trade-off.

The critical dependent variable of the Simon task was the difference between the mean response times to incongruent stimuli and congruent stimuli. The reliability of this measure was satisfactory (.92). This was taken to measure the interference between the dominant

1
2
3 response and correct response to the incongruent stimuli, interference that should require
4
5 inhibitory control to resolve. The distribution was examined, was found to be skewed, so was
6
7 square root transformed, resulting in a normal distribution.
8
9

10 11 12 13 14 Theory of Mind tasks

15 16 17 L1 VPT

18
19
20 Data trimming was conducted on correct responses only on the matching trials (4.78% of the
21
22 data were incorrect responses). Response times that were 2.5 standard deviations away from
23
24 the mean were eliminated (2.04% of the data; in line with Qureshi et al., 2010) and so were
25
26 response omissions due to the timeout procedure (responses over 2000ms; 0.47% of the data)
27
28 for a total of 3.92% of all trials. The data were analysed using a 2 x 2 repeated-measures
29
30 ANOVA, with consistency (consistent v inconsistent) and perspective (self v other) as the
31
32 factors. The measure first investigated was response time in each of the conditions.
33
34
35
36
37
38
39
40

41 There was a main effect of consistency ($F_{(1, 141)} = 288.59, p < .01, \eta_p^2 = 0.67$), with the
42
43 response time in the inconsistent condition significantly higher than that in the consistent
44
45 condition. There was no effect of perspective ($F_{(1, 141)} = .85, p = .36, \eta_p^2 = .01$). There was a
46
47 significant interaction between consistency and perspective ($F_{(1, 141)} = 63.52, p < .01, \eta_p^2 =$
48
49 0.31 ; see Figure A6) that was analysed further using simple main effects.
50
51

52 For both other and self-perspective judgments, response times to inconsistent trials were
53
54 significantly longer than for consistent trials (p 's $< .01$). For consistent trials, self-perspective
55
56 judgements were significantly longer than other perspective judgement trials ($p < .01$),
57
58
59
60

whereas for inconsistent trials, other perspective judgements were significantly longer than self-perspective judgements ($p < .01$)

Figure A6: Response times (bars = standard deviation) by condition and trial

The errors (not trimmed) in each condition were examined using an identical 2 x 2 repeated measures ANOVA. There was a main effect of consistency ($F_{(1, 141)} = 176.31, p < .01, \eta_p^2 = .56$), with more errors in the inconsistent condition than in the consistent condition. There was again no effect of perspective ($F_{(1, 141)} = 1.09, p = .30, \eta_p^2 = .01$). There was a significant interaction between consistency and perspective ($F_{(1, 141)} = 14.46, p < .01, \eta_p^2 = .09$), investigated further using simple main effects (see Figure A7).

For both other and self-perspective judgments, there were more errors on inconsistent trials than on consistent trials (p 's $< .01$). For consistent trials, there were more errors for self-perspective judgements than for other perspective judgement trials ($p < .01$), whereas for

inconsistent trials, there were more errors for other perspective judgements than for self-perspective judgements ($p < .05$)

Figure A7: Visual perspective error proportions (bars = standard deviation) by condition and trial

There was no difference in either response time or error rate between the participants taking their own perspective (self condition) or taking the avatar's perspective (other condition), indicating that in general there was no difficulty in taking one perspective over another. Other perspective trials show higher response times and error rates than self perspective trials, possibly due to greater interference of the self perspective in the inconsistent trials only.

This suggests that the L1 VPT was showing similar patterns to the original study of Samson et al. (2010).

The critical dependent variables for the task were calculated as per Bukowski & Samson (2017), resulting in a Conflict Index (inconsistent – consistent perspectives) and a Focus Index (self-perspective – other perspective), using Inverse Efficiency Scores (IES; response

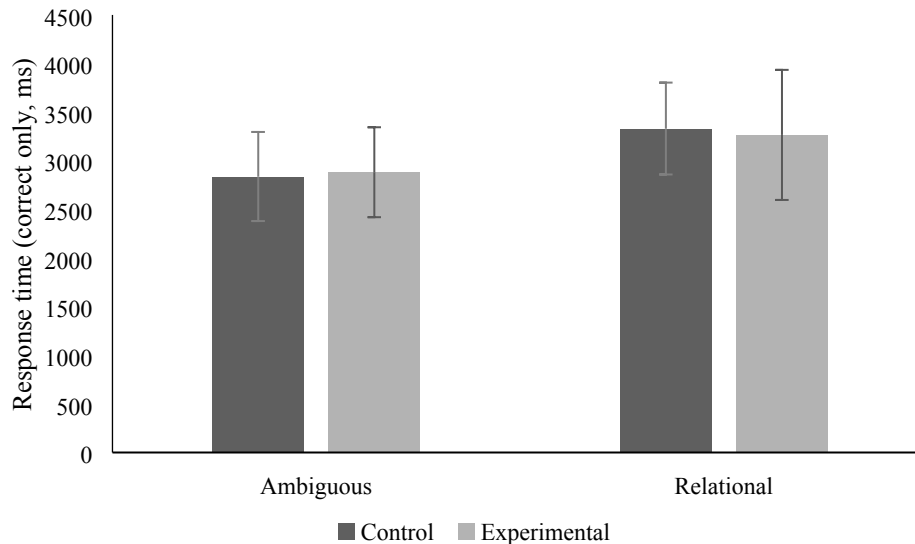

1
2
3 time / 1 – error rate)⁵. A higher value in the Conflict index indicated greater difficulty in
4
5 handling conflicting perspectives, while positive values in the Focus index indicated better
6
7 performance in taking the other person's perspective than the self- perspective (more
8
9 altercentric rather than egocentric). Results showed that the mean Conflict Index for
10
11 participants was .21 (SD = .13), with an excellent reliability of .85, and the mean Focus Index
12
13 was -.004 (SD = .13), with again an excellent reliability of .88. The variances were adjusted
14
15 to within a 10:1 ratio of the other task measures (Kline, 2005).

25

26 Director Task

27
28
29 For the response time analyses, the data were trimmed by condition for each participant
30
31 individually, looking at correct responses only (12.5% were incorrect responses to the
32
33 competitor item, 1.4% were responses to another object). Response time values that were
34
35 more than three standard deviations away from the condition mean for a participant were
36
37 replaced by the cut-off value (of three standard deviations from the condition mean). This
38
39 was done for 0.48% of trials. The data were analysed using a 2 x 2 repeated measures
40
41 ANOVA, trial type (control v experimental) and condition (ambiguous v relational).
42
43
44 Response time was looked at first, with correct responses only used. There was no effect of
45
46 trial type ($F_{(1, 141)} = .12, p = .73, \eta_p^2 = .00$). There was an effect of condition ($F_{(1, 141)} =$
47
48 $187.23, p < .01, \eta_p^2 = .59$), with the response time to ambiguous trials being significantly
49
50 faster than to relational trials (see Figure A8). There was also a marginal significant
51
52
53
54
55

56
57 ⁵ Use of IES is not recommended if speed-accuracy trade-offs are shown (indicated by no positive correlation
58 between response times and error rates) and if the average error rate is above .10 (c.f. Bukowski & Samson,
59 2017). The correlation between response time and error rate was positive ($r(142) = .20, p < .01$), and the mean
60 error rate across conditions was 0.06 (standard deviation = 0.07), meaning both recommendations for using IES
were met.

1
2
3 interaction between trial type and condition ($F_{(1, 141)} = 3.71, p = 0.06, \eta_p^2 = .02$). These
4
5 findings, compared against the error findings described below, show no indication of a speed-
6
7 accuracy trade-off.

56
57 The error rate was then examined with a series of t-tests, as no errors made in the control
58 conditions (error data were not trimmed). A one-sample t-test (with a theoretical value of
59 zero) showed that significantly more errors than zero were made in the experimental
60 condition ($t(141) = 12.89, p < .01$, with a mean difference of 3.94 (SD = 3.59)). A paired-
sample t-test showed there was also an effect of condition in the experimental trials ($t(141) =$
 $-8.88, p < .01$), with significantly more errors in the relational condition than in the
ambiguous condition.

For the ambiguous trials there were significantly more errors than zero ($t(141) = 11.36, p <$
 $.01$, with a mean difference of 1.17 (SD = 1.21)). There were significantly more errors than

1
2
3 zero in the relational trials ($t(141) = 12.12, p < .01$, with a mean difference of 2.77 (SD =
4
5 2.68)). These differences can be seen in Figure A9.
6
7
8

29 Figure A9: Mean number of errors (and standard error) in Director task by condition and trial type

30
31
32 The control condition was expected to have no errors and a faster response time due to there
33 being no competing item for the item description given by the instructor. The relational trials
34 were slower and resulted in more errors than the ambiguous trials. This may be due to there
35 being more items that the participant is cued to in the relational trials (for example in the
36 experimental grid where the critical instruction is ‘move the small ball...’, there are three
37 different sized balls present) compared to in the ambiguous trials (where in an experimental
38 grid, where the critical instruction is ‘move the mouse...’, there is a computer mouse and a
39 mouse, so there are only two potential items). The additional item that the participant must
40 consider in relational trials may explain the increased response times, and perhaps the
41 increased error rate.

2
3 The critical dependent variables for the Director task were the error rates of the relational and
4
5 ambiguous trials. These were expected to measure the participants' failure to use their theory
6
7 of mind. Both the distributions of the dependent variables were skewed, and they were both
8
9 square root transformed (ambiguous with a constant of one to remove negative values). This
10
11 resulted in adequately normal distributions for both dependent variables. The reliability of the
12
13 ambiguous measure was borderline satisfactory (.59), though the reliability of the relational
14
15 ambiguous measure was borderline satisfactory (.59), though the reliability of the relational
16
17 measure was excellent (.83).

Appendix A4

Executive task discussion

An initial correlation matrix including the Simon task is shown in Table 1. There were no correlations between the Simon task and any other task, so this was dropped from the final analyses.

Table 1. Correlation matrix between variables

	<u>Simon task</u>	<u>Shape Matching</u>	<u>Go NoGo</u>	<u>Go NoGo (picture)</u>	<u>Stop-Signal</u>	<u>Director Task (ambiguous)</u>	<u>Director Task (relational)</u>	<u>Visual Perspective (Conflict)</u>
<u>Shape-Matching</u>	.07							
<u>Go NoGo</u>	.11	-.04	=					
<u>Go NoGo (picture)</u>	.03	.00	.23**	=				
<u>Stop-Signal</u>	.14	.15	.18*	.08	=			
<u>Director (ambiguous)</u>	-.09	.09	.00	.34**	.02	=		
<u>Director (relational)</u>	.04	.29**	.01	.25**	.05	.65**	=	
<u>Visual Perspective (Conflict)</u>	.12	.06	.14	.00	.24**	-.03	-.04	=
<u>Visual Perspective (Focus)</u>	.07	-.02	.08	-.04	.02	.02	-.03	-.18*

Final R results from the path analyses showed a correlation between the Go / No-Go (picture) and Go / No-Go tasks, and between the Go / No-Go (picture) and the SST. There were no correlations with the Shape-matching task. While we predicted that the executive tasks would all intercorrelate as they all require response-distracter inhibition (as per Friedman & Miyake, 2004), the specific nature of the inhibition required by these varying tasks may explain this pattern of correlations. The Go / No-Go tasks both involve selecting relevant *responses* (i.e., to respond (go) or not (no-go) to the stimuli). Likewise the SST involves selecting the appropriate response to a given stimuli (whether to respond (go) or inhibit their response (stop) depending on whether there is a stop-signal). On the other hand, the Shape-matching

1
2
3 task involves selection of relevant and ignoring of irrelevant *information*, whereby the
4
5 participant needs to ignore the distracter shape and select their response based on the relevant
6
7 target shape. This may explain why responses on shape matching were not related with the
8
9 other executive measures.
10
11
12
13
14
15

16 The nature of the ToM tasks may also explain the relationships found with the different
17
18 executive tasks. As noted, L1 VPT performance, particularly on the Conflict index, may be
19
20 related to the effect of self/other consistency on selection of a response (Apperly, 2010;
21
22 Qureshi et al., 2010; McCleery et al., 2011), rather than on selection of information or any
23
24 integration. As such it is perhaps unsurprising that Conflict index of the L1 VPT is only
25
26 related to the SST. However, the Director task requires integration of perspective and
27
28 instruction, which may involve selection of relevant information and also response selection.
29
30 This perspective would explain the relationship between to the Go / No-Go (picture) and
31
32 Shape-matching task. The latter may be related to Relational trials of the Director task due to
33
34 there being potentially three referent objects (rather than two as in ambiguous trials).

Appendix B (models prior to final)

Initial Model

The initial model shown in Figure 1 showed no relationship between the Go / No-Go or Stop-Signal tasks and either of the Director task variables. The Shape-Matching task only predicted performance on the relational variable of the Director task. The Go / No-Go (picture) task predicted performance on both variables of the Director task. The Stop-Signal Task predicted performance on the L1 VPT Conflict Index. All parameters (standardised and unstandardized path coefficients, covariances and correlations, variances and squared multiple correlations) are shown in Table 1.

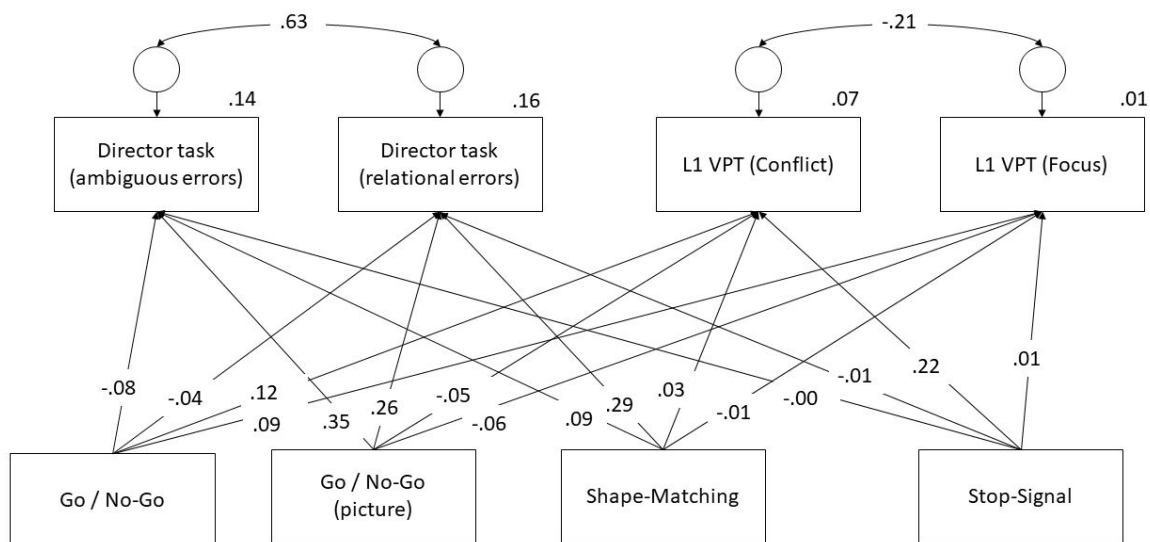

Figure 1. Initial Model (standardised coefficients)

Table 1 shows significant correlations between the pairs of variables for each ToM task, and that the error terms and variances were all significant. Approximately 16% of the relational variable and 14% of the ambiguous variable were accounted for by this initial model. The model (**Error! Reference source not found.**) however, was not a good fit to the actual data.

Model 2

Non-significant paths were removed, resulting in the model shown in Figure 2.

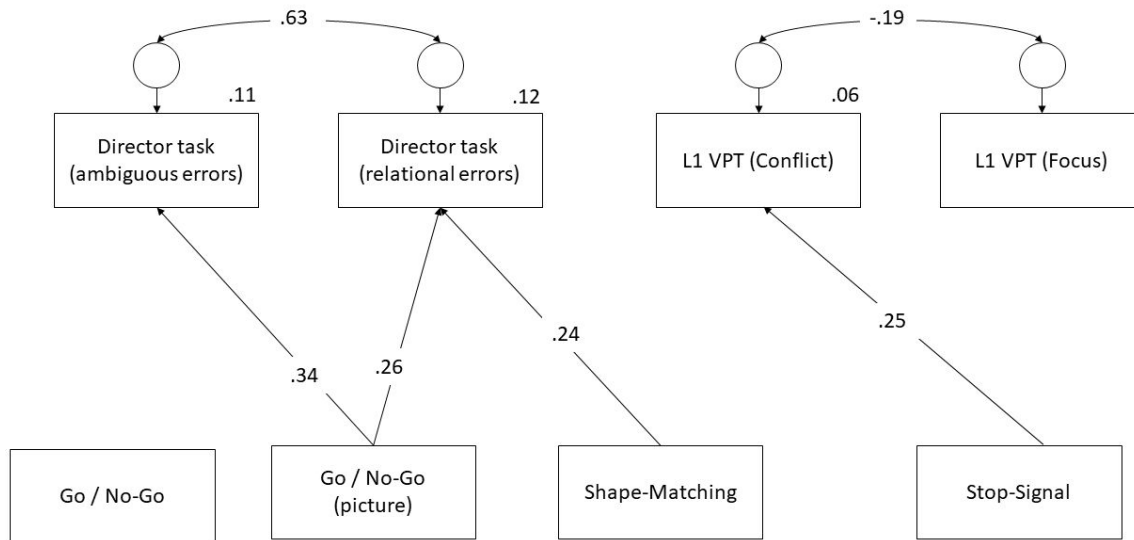

Figure 2. Model 2 (standardised coefficients)

Table 2 shows the model parameters in full. Removing the non-significant parameters did not affect the individual parameters or the model fit (**Error! Reference source not found.**), with the AIC value reducing from the initial model.

Appendix C (all models)

The following analyses used interference measures for self (altercentric interference from the avatar perspective) and other (egocentric interference from the self perspective) for the L1 VPT task. These were calculated based on reaction times for correct trials only and were “inconsistent perspective condition – consistent condition” for self and other trials separately.

After variance adjustment and transformations, the final descriptive statistics for the dependent and independent variables were as shown in Table 1.

Table 1. Final task descriptives

Measure	M (SD)	Variance	Reliability ¹
Shape-Matching (ms) (square root transformation)	21.56 (4.88)	23.77	.92
Go / No Go (FAR)	4.28 (2.12)	4.51	.93
Go / No Go (picture) (FAR; Bird/Mammal) ²	6.17 (3.05)	9.28	.74
Stop-Signal (SSRT) (log 10 transformation)	16.33 (6.74)	45.52	.99
Director Task (errors) (log 10 transformation)			
Ambiguous	2.34 (2.41)	5.79	.59
Relational	2.75 (2.66)	7.07	.83
Visual Perspective measures (ms)			
Egocentric interference	4.88 (5.62)	31.63	.63
Altercentric interference	8.52 (6.33)	40.08	.43

An initial correlation matrix between the variables is shown in

Table 2. For the inhibitory control tasks, positive correlations were shown between the Shape-Matching and Stop-Signal tasks, the Go/No-Go and Go/No-Go (picture) tasks and the Go/No-Go and Stop-Signal tasks. A positive correlation was shown between the Director task variables, and a negative one between the L1 VPT variables. The Shape-Matching task had

¹ Split-half reliabilities

² As FAR for the bird and mammal trials were significantly correlated and followed the same pattern, they were collapsed to form a single FAR for the go / no go (picture) task

positive correlations with both the Director (relational) variable, while the Go/No-Go (picture) task had positive correlations with both measures of the Director task. The Stop-Signal task also had a positive correlation with the L1 VPT (Conflict) variable.

Table 2. Correlation matrix between variables

	Shape Matching	Go NoGo	Go NoGo (picture)	Stop-Signal	Director Task (ambiguous)	Director Task (relational)	Visual Perspective (Conflict)
Go NoGo	-.04	-					
Go NoGo (picture)	.00	.23**	-				
Stop-Signal	.15	.18*	.08	-			
Director (ambiguous)	.09	.00	.34**	.02	-		
Director (relational)	.29**	.01	.25**	.05	.65**	-

Visual Perspective Altercentric	.16	.03	.01	.14	-.12	-.07	.24**

* $p < .05$, ** $p < .01$

Models

Analyses were carried out using AMOS 25.

Initial Model

The initial model shown in Figure 1 showed no relationship between the Go / No-Go or Stop-Signal tasks and either of the Director task variables. The Shape-Matching task predicted performance on the relational variable of the Director task. The Go / No-Go (picture) task predicted performance on both variables of the Director task. The Stop-Signal Task and Shape-Matching task predicted performance egocentric interference. All parameters

(standardised and unstandardized path coefficients, covariances and correlations, variances and squared multiple correlations) are shown in Table 1.

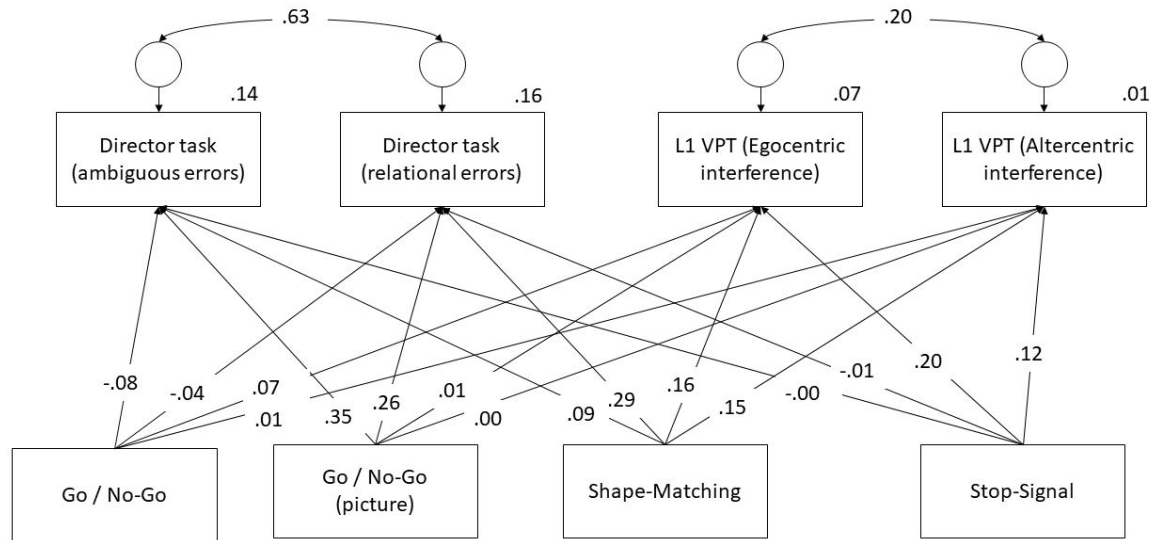

Figure 1. Initial Model (standardised coefficients)

* $p < .05$, ** $p < .01$, *** $p < .001$

Table 3 shows significant correlations between the pairs of variables for each ToM task, and that the error terms and variances were all significant. Approximately 16% of the relational variable and 14% of the ambiguous variable were accounted for by this initial model. The model (see Table 6) however, was not a good fit to the actual data.

Model 2

Non-significant paths were removed, resulting in the model shown in Figure 2. Doing this did not significantly affect the model fit ($\chi^2(11) = 8.85, p = .64$).

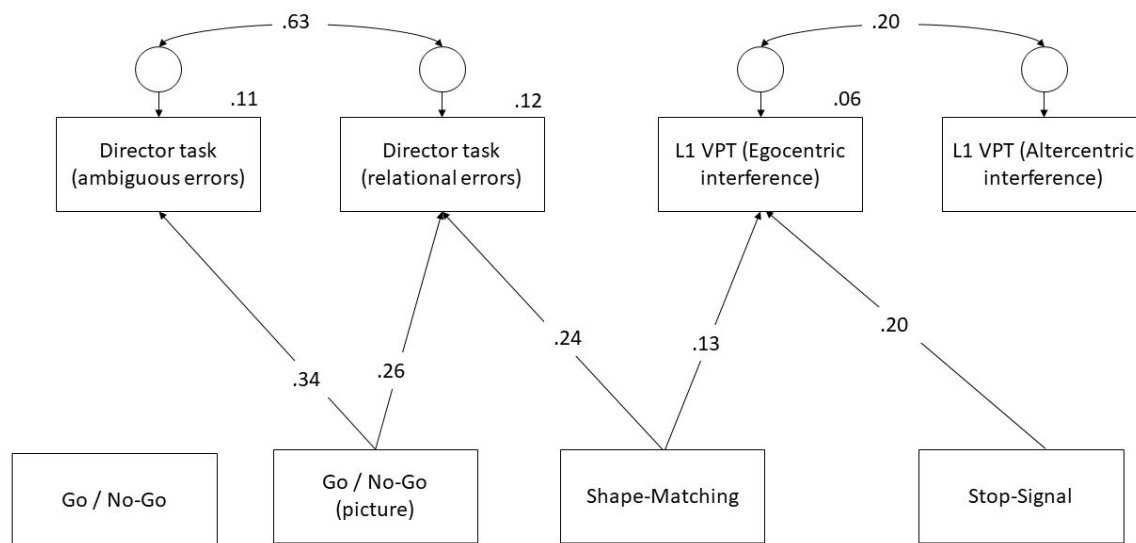

Figure 2. Model 2 (standardised coefficients)

Table 2 shows the model parameters in full. Removing the non-significant parameters did not affect the individual parameters or the model fit (Table 6), with the AIC value reducing from the initial model.

Table 4. Parameter estimates for Model 2

Path	Unstandardised Estimate (Standard Error)	Standardised Estimate

Model 3 (Final)

The non-significant path between the Shape-Matching task and egocentric interference was removed, and correlations added between the Go / No-Go (picture) and Go / No-Go tasks and also between the Go / No-Go and Stop-Signal tasks (as per modification indices), resulting in the final model in Figure 3. The model fit (as per AIC values) was improved.

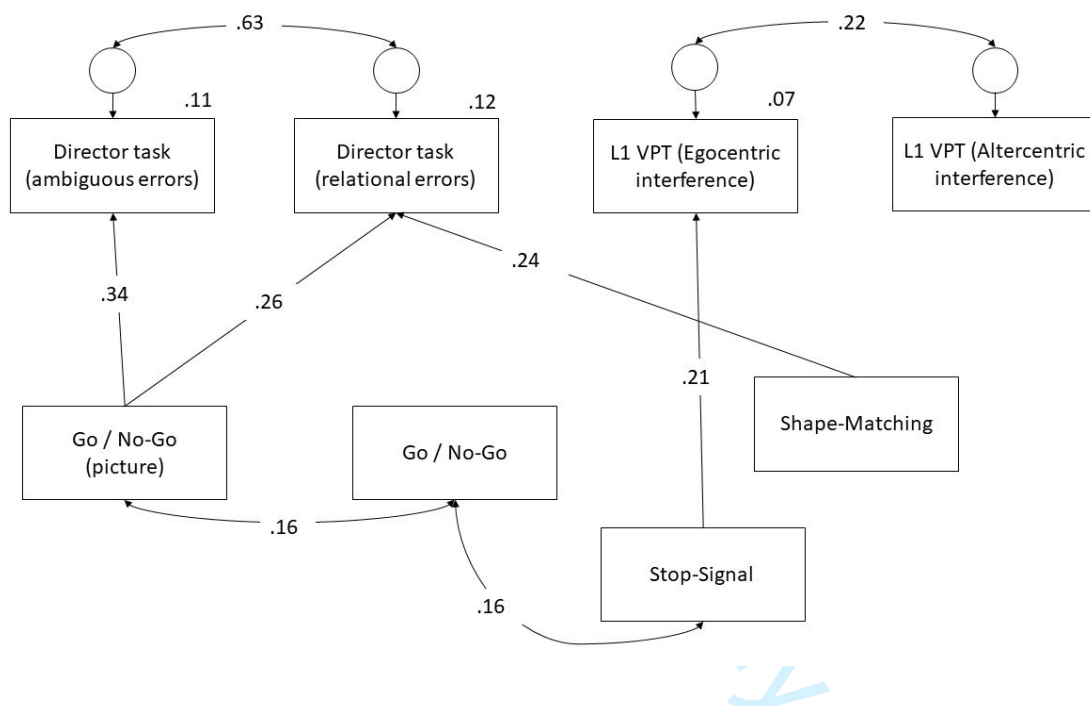

Figure 3. Final model (standardised coefficients)

Table 5 shows the model parameters in full.
